Many machine learning methods have been applied to miRNA discovery (see (Demirci *et al.*, 2017) for a review), most often trained using data from miRBase as training data. Negative datasets are usually obtained from coding regions (or equivalently, exons), or by random sampling from whole genomes. It has been suggested that an average decision tree is best, and generalizes across species. Recently, a number of groups have attempted to determine which of the many proposed features are most discriminative. Agarwal *et al.* (2015) found that 3'-UTR site abundance, predicted seed-and downstream pairing stability, the base at position 1 and 8 of the miRNA seed sequence, the base at position 8 of the target site, local UA content, predicted structural accessibility, distance from the miRNA site to the stop codon of polyA site, site conservation, ORF length, 3'UTR length, and the number of offset sites in the UTR are the most important features in identifying miRNA targets. Lopes *et al.* (2014) found that minimum predicted free energy index, ensemble free energy, normalized number of sequence variants, normalized Shannon entropy, and normalized base-pair distance were the most important features in a random forest approach. Tran *et al.* (2015) found, using a boosted support vector machine approach, that the most important features are folding free energy of the longest nonexact stem, maximum number of consecutive G's in the longest nonexact stem, percentage of CC and GA dinucleotides, maximum number of consecutive C's, maximum number of consecutive G's in the hairpin, percentage of G-U pairs, folding free energy normalized by hairpin size, percentage of paired U, average folding free energy, percentage of unpaired-unpaired A-paired triplets, and size of bulges. As just these three examples show, there is considerable disagreement, even today, over what features are most relevant and powerful for miRNA target identification.

Databases/Resources

There are many online resources related to miRNA (for a recent review see (Singh, 2017)). A large fraction of these have been created for a particular organism or purpose, and then not updated. Below, we give our recommendations for the most useful and reliable resources (in our opinion).

- MiRBase (miRBase, 2016; Kozomara and Griffiths-Jones, 2013) is the original miRNA resource and still hosts the miRBase registry which provides unique names for novel miRNA genes prior to publication. Release 21 of miRBase contains 28,645 entries from 223 species, including extensive annotation of functions, experimental evidence, and links to other databases.

- DIANA-TarBase ([Paraskevopoulou, 2016](#); [DIANA-TOOLS, 2016](#); [Vlachos et al., 2015](#)) focuses on experimentally validated miRNAs and includes more than half a million experimentally supported miRNA-mRNA interactions. In addition TarBase includes computational predictions made with the MicroT-CDS method.
- Plant Non-coding RNA Database ([PNRD, 2016](#); [Yi et al., 2014](#)) focuses on all types of non-coding RNAs in plants, not just miRNAs. Since miRNAs are structurally somewhat different in plants, a plant specific resource is sometimes useful. The earlier Plant MicroRNA Database (PMRD) appeared to be inactive at the time this article was written.
- Rfam ([Rfam, 2017](#)) contains a large amount of information about miR families, including sequences, species of occurrence, secondary structure (usually predicted), and matching motifs.

lncRNA

Biological Background

By definition, long noncoding RNA (lncRNA) collectively refers to the group of transcribed RNAs, with a length longer than 200 nucleotides and low coding potential. However, the 200 nucleotide threshold is an arbitrary threshold, which was selected based on a convenient biochemical cutoff in RNA isolation protocols. BC1 and snaR, for example, are examples of ncRNAs that are shorter than 200 nucleotides but still classified as lncRNAs. Therefore, in 2011, Amaral *et al.* refined this definition: lncRNAs are noncoding RNAs that may have a function as either primary or spliced transcripts, that do not encode proteins, and are neither members of structural RNA families (tRNAs, snoRNAs, spliceosomal RNAs, etc.), nor processed into known classes of small RNAs, such as microRNAs (miRNAs), piwi-interacting (piRNAs) and small nucleolar RNA (snoRNAs)^[1]. Clearly this is still somewhat unsatisfying as lncRNAs are primarily defined as those that do not belong to known classes.

Because of the generous definition, lncRNAs are diverse in their biogenesis, stability, sub-cellular localization, evolutionary conservation, structures and functions ([Ayupe et al., 2015](#); [Johnsson et al., 2014](#)). lncRNAs are typically capped, spliced, and polyadenylated. Compared with mRNAs, lncRNAs have relatively a lower expression level and lower stability. They are more tissue specific and cell-type specific, and are often expressed in a narrower time window. lncRNAs are mostly located in the nucleus, presumably to regulate gene expression, at the epigenetic level, but a minority of lncRNAs are present in the cytoplasm where they regulate translation. For example, Xist is a well-studied lncRNA that is involved in X inactivation in placental mammals. Xist is localized in the nucleus, and is highly expressed from the inactivated X chromosome at the onset of X chromosome inactivation. Xist binds at many locations in the inactivated X chromosome (by an, as yet, not well understood process) and recruits silencing factors such as the Polycomb repressive complex 2 (PRC2) to silence X chromosome genes ([Brown et al., 1992](#); [Clemson et al., 1996](#)).

Beyond primates, little sequence conservation is typically observed in lncRNAs. Unlike mRNAs, the lack of conservation in the sequences of lncRNAs does not indicate a lack of common functions; An increasing number of examples have shown that lncRNAs are conserved in structure rather than sequence, and the secondary (or higher) structure of lncRNAs constitutes the main functional unit. For example, HOTAIR is a trans-acting lncRNA whose sequence is poorly conserved in mammals beyond primates ([Bhan and Mandal, 2016](#)). Covariance analysis across 33 mammalian sequences of HOTAIR revealed a significant number of covarying positions and half-flips localized in all four domains of HOTAIR, which maintain a similar structure ([Somarowthu et al., 2015](#)).

According to NONCODE (v 5.0, a database of lncRNAs documented in the literature), 354,855 lncRNAs have been identified in 17 species. However, the functional roles of these lncRNAs remain mostly unknown. According to lncRNAdb (a database of eukaryotic lncRNA annotations), fewer than 300 have annotated functions confirmed by overexpression or knockdown experiments. lncRNAs, in general, can either repress or activate gene expression, which is associated with cell-fate programming ([Flynn and Chang, 2014](#)) and numerous human diseases ([Esteller, 2011](#)). The number of lncRNAs whose mechanisms are known in detail are even more limited, less than 20. But these examples have already shown that lncRNAs are involved in important biological processes, such as genomic imprinting, chromatin remodeling, post-transcriptional RNA processing, and regulation of translation. Based on our current knowledge, lncRNAs consummate their regulatory roles in 3 major ways: 1). Decoys: that is they bind to regulatory proteins and preclude their access to DNA; 2). Scaffolds: they recruit epigenetic complexes to regulate chromatin states; and 3). Guides: the lncRNA binds proteins and guides the ribonucleoprotein complex to a target ([Rinn and Chang, 2012](#)). PANDA is an example of a lncRNA decoy. It sequesters a transcription factor called NF-YA, and keeps NF-YA from binding to its target genes, and prevents p53-mediated apoptosis ([Hung et al., 2011](#)). HOTAIR, which is located in the HOXC cluster, is an example of a lncRNA scaffold. It can simultaneously bind PRC2 in its 5' domain and LSD1 in its 3' domain. PRC2 has the function of histone H3 lysine-27 trimethylation, and LSD1 is involved in demethylation of histone H3 at lysine 4. This combination of interactions ensures epigenetic silencing of multiple cancer related genes ([Hajjari and Salavaty, 2015](#)). As mentioned above, Xist is an example of a lncRNA guide. Xist recruits Polycomb 1 and 2 complexes and guides them to the inactivated X chromosome to establish and maintain its silencing. Because the mechanisms of so few lncRNAs are known in detail, it is likely that many other mechanisms will be uncovered, ultimately revealing a more complex picture of the role of lncRNAs in regulatory networks.

Classification of lncRNAs

In GENCODE ([GENCODE, 2017](#)), lncRNA is classified based on its genomic location with respect to nearby protein-coding genes. This is also one of the most commonly used methods to classify lncRNAs. Initially, lncRNAs are classified as either intergenic

lncRNAs or intragenic lncRNAs. The transcripts of Intergenic lncRNAs (lincRNAs) do not overlap protein coding transcripts, while intragenic lncRNAs are transcribed from regions that overlap protein coding genes and can be further classified into sense and antisense lncRNAs. Sense lncRNAs are transcribed from regions of protein-coding genes on the same strand as the mRNA. They can overlap with both introns and exons of protein-coding genes. Totally Intronic RNAs (TINs), are lncRNAs that are located entirely within intronic regions of protein-coding genes. Partially Intronic RNAs (PINs), (Nakaya *et al.*, 2007) are lncRNAs that partially or entirely cover the introns of protein-coding gene. Antisense lncRNAs, or Natural Antisense Transcripts (NATs), are lncRNAs transcribed from the opposite strand of protein-coding genes.

Another way to classify lncRNAs is to distinguish their roles in the regulation of gene expression, distinguishing cis-acting and trans-acting RNAs. Cis-acting lncRNAs regulate the expression of genes that are positioned at the same, or a nearby, genomic locus. They may function through transcriptional interference or chromatin modification. Promoters and enhancers are two natural targets of cis-regulatory lncRNAs, which can recruit transcription factors, or chromatin modification complexes which remodel the structure of adjacent protein coding genes, to increase transcription. Promoter lncRNAs (sometimes called bidirectional promoter lncRNAs), plncRNAs, are transcribed from regions near the transcription start site (usually within 1500 bp of the transcription start site) of protein-coding genes, whereas enhancer lncRNAs (elncRNAs) are located up to 1 Mbp upstream or downstream of the regulated gene. Trans-acting lncRNAs can control the expression of a gene at an independent loci, for example, genes on a different chromosomes.

Discovery and Exploration of lncRNAs

Determining the nature and possible biological functions of lncRNAs has become a focus of intense research. Expression profiling is often a first step in uncovering the function of a lncRNA. Identifying differentially expressed lncRNAs in developmental stages or conditions can imply their potential functions. Alternatively, an informatic method termed “Guilt by Association” identifies functions of lncRNAs by looking for protein-coding genes whose expression is significantly correlated with a lncRNA (Guttman *et al.*, 2009).

Even though some researchers have successfully identified lncRNAs using polyadenylated RNA sequencing (mRNA-Seq), total cellular RNA sequencing (total RNA-Seq) is the usually the method of choice for comprehensive expression profiling of lncRNAs. This is because some lncRNAs, particularly elncRNAs, may not be spliced or polyadenylated. By using total cellular RNA-Seq, both mRNAs and lncRNAs can be identified, regardless of whether they are polyadenylated.

In the following section, we describe a computational pipeline for the identification of lncRNAs using total RNA-Seq data.

1. First the RNA-Seq reads must be mapped, separately, to a reference.
 - a. If using a reference genome, reads are first mapped to the genome using an intron aware mapper (e.g., using Tophat2 (Kim *et al.*, 2013). Transcripts from different samples are merged (e.g., using Cufflinks (Trapnell *et al.*, 2012)).
 - b. If not using a reference genome, reads from all samples are combined to construct a *de novo* transcript assembly (e.g., using Trinity (Grabherr *et al.*, 2011)).
2. Reads from the individual samples are separately mapped to the reference.
3. Possible protein coding transcripts are excluded by multiple filtering steps, for example, removing
 - a. annotated protein coding transcripts,
 - b. transcripts with high coding potential (e.g., using the Coding Potential Calculator (Kong *et al.*, 2007)),
 - c. transcripts that match conserved known proteins or motifs (e.g., using Blastx (Altschul *et al.*, 1997)),
 - d. transcripts that have a high rate of synonymous versus nonsynonymous substitutions (e.g., using PhyloCSF (Lin *et al.*, 2011)).
4. ChIP-Seq (Chromatin Immunoprecipitation Sequencing) can be used to identify lncRNAs involved in gene activation involving transcription factors, or histone modification.

lncRNA Databases/Resources

Many online resources are available for lncRNAs. As with miRNAs, the spectrum of resources rapidly changes as many database are created for particular purposes, but not maintained over time. In Table 1 we list a few of the currently active resources. Online searches for “lncRNA database” or similar terms will typically provide an updated list of resources, and a list is also maintained on Wikipedia (see the source citation in Table 1).

Closing Remarks and Future Directions

MicroRNA and lncRNA play important roles in biological regulation. In the case of miRNA, a good deal is known about the identity of miRNAs and their targets. In spite of this depth of knowledge, there are a dismaying number of online resources that have been created and, apparently, never updated. This makes it particularly hard to make recommendations about electronic resources; miRBase, Diana-TarBase, and Rfam seem to have the best long-term availability.

Table 1 lncRNA databases and resources

Database	Species	Last update	URL http:// Description
lncRNAdb	69 species	23-Nov-15	www.lncrnadb.org Includes lnc RNAs shown to be functional by overexpression or knockdown experiments
RNAcentral	37 species	1-Apr-17	rnacentral.org Combines 25 well maintained ncRNA databases. Provides integrated text search, sequence similarity search, and programmatic data access (API)
NONCODE	17 species	6-Sep-17	www.noncode.org Includes lncRNAs from published literature, GenBank, and specialized Databases such as Ensembl, RefSeq, lncRNAdb and LNCipedia. Functions of lncRNA are predicted by lnc-GFP
LNCipedia	Human	4-May-17	lncipedia.org Includes 146,742 annotated human lncRNAs. Provides basic transcript information, predicted 2° structure, calculated protein coding potential, and predicted microRNA binding sites
GreenC	45 species	19-Sep-16	greenc.sciencedesigners.com Includes lncRNAs annotated in plants and algae that are identified by using self-developed pipelines. Provides information about sequence, genomic coordinates, coding potential, and predicted folding energy
PLAR2	17 vertebrates	Unknown	www.weizmann.ac.il/Biological_Regulation/IgorUlitsky/pipeline-lncrna-annotation-rna-seq-data-plar Includes lncRNAs identified using self-developed pipelines. 3P-seq information are included
lncRNADisease	human	26-Jul-17	www.cuilab.cn/lncrnadisease Includes experimentally supported lncRNA-disease association data and lncRNA interactions in various levels, including protein, RNA, miRNA, and DNA
lnc2Cancer	human	4-Jul-16	www.bio-bigdata.com/lnc2cancer A manually curated database that include 1488 entries of associations between 666 human lncRNAs and 97 human cancers

Source: Wikipedia (http://en.wikipedia.org/wiki/List_of_long_non-coding_RNA_databases).

The situation with lncRNAs is very different. Very few lncRNAs have experimentally determined functions, and many have been predicted only computationally. We expect that methods for identifying lncRNA and for assigning functions will develop rapidly over the next few years as more biological information about their function becomes available. In the meantime, it is likely that there will considerable flux in the availability of available websites and tools.

Gene-Gene Interactions: An Essential Component to Modeling Complexity for Precision Medicine

Molly A Hall, The Pennsylvania State University, University Park, PA, United States

Brian S Cole and Jason H Moore, University of Pennsylvania, Philadelphia, PA, United States

© 2019 Elsevier Inc. All rights reserved.

Genetic Interaction Modeling is Needed to Better Understand and Predict Complex Diseases

Imagine you are prescribed a medication in your doctor's office and a warning pops up on the computer screen as your doctor enters the prescription into your electronic health record. This warning tells your doctor that you have a genetic variant that predisposes you to serious side effects from the medicine being prescribed. This scenario is the goal of precision medicine: that medications, therapies, disease risk assessment, and interventions are informed by each individual patient's genetic background as well as their environmental history. Presently, however, clinicians typically do not have access to patient genetic data or a comprehensive list of past and current environmental exposures. More importantly, even if warning systems like these were available in every clinic, this scenario would not be possible for every drug therapy and disease because, to date, there is simply not enough known about the complex mechanisms that lead to common diseases and adverse drug reactions.

For many rare, Mendelian disorders like cystic fibrosis and Huntington's disease, the genetic component has been largely explained. These diseases involve one or a small set of rare but highly penetrant mutations. For example, early linkage studies found mutations in *cystic fibrosis transmembrane conductance regulator* (*CFTR*) that lead to cystic fibrosis (Kerem *et al.*, 1989; Riordan *et al.*, 1989; Rommens *et al.*, 1989). Conversely, due to their complex etiologies, the genetic basis of common traits like type 2 diabetes, height, body mass index (BMI), and many cancers have remained elusive.

Genetic association studies are often used to study complex traits like these. In a genetic association test, allele frequencies for a locus are compared between individuals who have a disease of interest (e.g., type 2 diabetes cases) and those who do not (e.g., type 2 diabetes controls). Before the advent of low-cost and high-throughput genotyping technologies, genetic association tests were performed for genetic loci that were predicted to be involved with a disease (candidate genetic association studies). Alternatively, genome-wide association studies (GWAS) allow agnostic testing of a set of single nucleotide polymorphisms (SNPs) across the genome to identify novel genetic regions predictive of disease.

GWAS have been successful at identifying numerous loci across the genome that are associated with a diverse and wide range of phenotypes. However, as predicted by Wang *et al.* (2005), if the odds ratios of all SNP-phenotype associations curated in the NHGRI GWAS Catalog (Welter *et al.*, 2014) are considered, the vast majority of SNPs have a low effect on the traits with which they are associated, and relatively few SNPs have a high effect (Wang *et al.*, 2005; Hall *et al.*, 2016a,b). Manolio *et al.* (2009) suggested a 2-fold risk increase (odds ratio of 2) as indicative of a variant exhibiting a large effect (Manolio *et al.*, 2009). Yet, the majority of GWAS-identified associations demonstrate an odds ratio less than 1.5, which has led many in the field to look beyond GWAS (Manolio *et al.*, 2009; Maher, 2008; Hall *et al.*, 2016a,b; Moore *et al.*, 2010).

Incorporating gene-gene interactions is an essential component to modeling the complexity that exists in biology and the processes that lead to common diseases. Gene products interact physically with one another or within one or multiple pathways. Further, physical interactions between and within DNA, RNA, and proteins are a major part of gene regulation (Martinez, 2002) and translation (Gallie, 2002). Considering loci individually does not allow for the complexity known to exist in molecular and cell biology and in physiology. Embracing complexity by exploring gene-gene interactions is likely to explain much of the yet unknown etiology of common diseases, as these complex traits arise from vastly dynamic and interconnected systems in biology. Such analyses will also identify the genotype combinations that confer the greatest risk to adverse health outcomes. Discussed in this article is the history of epistasis, examples of genetic interactions in model systems and humans, major challenges to identifying gene-gene interactions and common methods for overcoming these challenges, as well as consideration of additional types of complexity that must be explored in combination with epistasis to further reveal the etiology of common diseases.

Historical Perspectives on Analysis and Interpretation of Gene-Gene Interactions

The analysis of gene-gene interactions long predated the elucidation of the structure of DNA. After the rediscovery of Mendel's pioneering experiments of pea crosses that spawned the field of genetics, an explosive period of genetic discovery, driven by experiments in model systems and mathematical analysis at the population level, dominated the first two decades of the twentieth century (Sturtevant, 2001). It was during this gilded age of genetics that pioneering analysis of model systems extended and refined Mendel's laws into a cohesive theory of genetics that formed the basis of our modern understanding. During this period, epistasis was discovered by William Bateson, the biologist who coined the term "genetics" to name the nascent field of the study of heritable variation (Bateson, 1909).

Bateson used the term "epistasis" to describe a cross between two strains in which the phenotypic distribution of the resulting offspring departs from the ratios expected by Mendel's laws (Cordell, 2002). Specifically, Bateson used the term epistasis to

describe one mutation blocking or masking the effects of another, hence the use of term “epistasis” which may be translated as “resting upon.” Bateson’s usage of the term epistasis described an interaction between two genetic variants in which one variant negates the effects of another (Phillips, 2008). This type of genetic interaction, sometimes called modification, was the first form of gene-gene interactions to be observed in experimental crosses. Working together with Reginald Punnett, Bateson developed a two-locus Punnett square to describe the phenotypic ratios of F_2 progeny from crosses of two strains of the flowering sweet pea *Lathyrus odoratus* which displayed a flower coloration trait only when two separate dominant alleles were present at separate loci (Sturtevant, 2001). This two-locus epistasis model extended Mendel’s original postulations of a two-locus model to incorporate an interaction between genetic variants, without which the phenotypic ratios of Bateson’s and Punnett’s sweet peas did not conform to Mendel’s laws.

Bateson and Punnett’s description of epistasis is the result of crosses between self-fertilizing strains of plants, which are essentially controlled for genetic background, allowing the analysis of the effects of one or a small number of genetic variants on visible phenotypes such as morphological traits. Natural populations of organisms, including humans and wild populations of other organisms which are used as model systems in experimental genetics, contain genetic variation across the genome, eliminating the ability to analyze the effects of one or a small number of genetic variants against a controlled background (Moore and Williams, 2005). The statistical geneticist R. A. Fisher extended the description of epistasis to populations which are not controlled for genomic background by defining “epistasis” as deviations from additivity in a linear model (Fisher, 1919). This definition of gene-gene interactions allows for the statistical detection of epistasis in a population which contains a large number of polymorphic sites in the genome by defining epistasis as a statistical deviation from additivity, a definition which incorporates the mean effect of two or more genetic variants in a given population of organisms (Doust *et al.*, 2014.). Importantly, Bateson’s definition of epistasis involved organisms which share almost all of their genome (inbred strains) and Fisher’s definition involved organisms which contain polymorphisms across the genome (wild populations). Modern scientists have synthesized these concepts into biological and statistical epistasis (Moore and Williams, 2005). Biological epistasis refers to experimental crosses in which the distribution of phenotypes in offspring deviate from Mendelian ratios (as described by Bateson and Punnett), and statistical epistasis indicates genetic effects which deviate significantly from additivity in highly polymorphic populations (as described by Fisher). As a hypothetical example to demonstrate statistical epistasis consider two loci: LocusA and LocusB. If the relationship between the two loci is additive, we would expect the combined effect of the two on a phenotype to be the addition of the main effect of LocusA and the main effect of LocusB. For example, if there is a 2-fold and 3-fold risk associated with the risk alleles for LocusA and LocusB, respectively, the additive result from both loci is a 5-fold increase risk. If the relationship is epistatic, however, the effect of the two loci together will significantly differ from the combined main effects of the two loci. In the scenario described, the presence of both risk alleles under an epistatic relationship could be a 15-fold risk increase; alternately, risk could decrease to 1.1-fold. In other words, when statistical epistasis occurs, there is a non-linear relationship between the effects of two or more loci when combined. While these two forms of epistasis are experimentally distinct, the underlying theory is identical: epistasis, defined broadly, is the interaction between distinct genetic variants (Phillips, 1998, 2008). This definition encompasses both statistical epistasis which might be detectable in population-scale studies and biological epistasis which might be observable in controlled crosses.

Epistasis research has continued to play a central role in genetics since the early work of Bateson, Punnett, Fisher, and others at the dawn of the twentieth century. An important application of epistasis to biological discovery came in the form of pathway ordering, in which multiple strains of a model organism are crossed together and phenotypes observed such that the ordering of a biological pathway becomes evident (Avery and Wasserman, 1992). This important genetic tool can be used to discover which gene products are upstream or downstream of other gene products, providing evidence of gene product function without molecular or biochemical analysis. This can be achieved by crossing together separate mutant strains of a model organism which display different phenotypes (Beadle, 1945). If a double mutant displays the same phenotype as one of the mutants does individually, one mutation likely occurs in a gene whose product functions downstream in a biochemical pathway. While this is certainly not always the case, epistasis as a tool for pathway ordering elucidated the ordering of mutations (and thereby their gene products, even if the molecular functions were only later established) in the biological pathways which control cell cycle in yeast, sex determination in *C. elegans*, embryonic development in *D. melanogaster*, and other pathways (Phillips, 2008).

As described by Moore (2003), epistasis is thought to be ubiquitous in biology (Moore, 2003; Templeton, 2000). Examples of epistasis have been observed in many model organisms (Mackay, 2014), including yeast (Wagner, 2000; Boone *et al.*, 2007; Tong *et al.*, 2004; Szappanos *et al.*, 2011; Moore, 2005; Baryshnikova *et al.*, 2013), *C. elegans* (Lehner *et al.*, 2006; Gaertner *et al.*, 2012; Byrne *et al.*, 2007), *D. melanogaster* (Horn *et al.*, 2011; Huang *et al.*, 2012; Lloyd *et al.*, 1998), *M. musculus* (Cheng *et al.*, 2011; Hanlon *et al.*, 2006; Gale *et al.*, 2009), and *A. thaliana* (Rowe *et al.*, 2008; Kroymann and Mitchell-Olds, 2005). While examples of epistasis have accrued in model organisms over the years, epistasis is not confined to Mendelian traits, for which a small set of highly penetrant mutations explain much of the variance in observed phenotypes. Epistatic interactions between genetic loci have been discovered in human traits ranging from blood types and eye coloration to complex, polygenic, and multifactorial traits such as disease susceptibility (Moore, 2005). Nelson *et al.* (2001) identified interactions between ApoB and ApoE in females as well as between the low-density lipoprotein receptor and the ApoAI/CIII/AIV complex in males for triglyceride levels (Nelson *et al.*, 2001). Interactions between SNPs in three estrogen metabolism genes, *COMT*, *CYP1B1*, and *CYP1A1*, were identified by Ritchie *et al.* (2001) that were predictive of sporadic breast cancer (Ritchie *et al.*, 2001). Further, a study by Hemani *et al.* (2014) identified and replicated a large number of genetic interactions involved in gene expression regulation (Hemani *et al.*, 2014).

Epistasis research was spawned shortly after the rediscovery of Mendel's foundational work that gave rise to the field of genetics and has found application in the understanding of how genetic variants interact to determine phenotypic outcomes. While genetic interactions have provided insight into traits which cannot be adequately explained by additive models or Mendelian ratios, epistasis research remains an active application of genetics in the modern scientific research enterprise. Particularly, detection of epistasis in studies of complex traits in humans presents methodological and computational challenges that remain an active area of development.

Major Challenges to Exploring Genetic Interactions and Common Solutions

Genome-wide association studies most commonly utilize regression to identify statistically significant genotype-phenotype associations and to quantify the certainty and effect size of the association. These regression analyses typically utilize multivariable linear or generalized linear models in which genotypes and covariates of interest such as age, gender, and Body Mass Index are represented as additive terms in a linear equation for which the parameters are estimated by regression. As described above, epistasis is defined as significant deviation from additivity. It is necessary to consider this definition when testing for epistasis using regression. Testing for independent locus main effects in regression, even at the genome-wide level with GWAS, typically involves a model such as $Phenotype \sim \beta_0 + \beta_1 SNP + covariates$. In this linear model formula, the main effect of a SNP (as represented by the parameter estimate of β_1 and its associated significance) on a phenotype (or outcome) of interest is tested. In GWAS, a model is tested for each SNP included in the data set. A likelihood ratio test is recommended when performing interaction tests using regression. The likelihood ratio test compares the difference between a full and reduced model, where the full model in this case is $Phenotype \sim \beta_0 + \beta_1 SNP + \beta_2 SNP2 + \beta_3 SNP1 \times SNP2 + covariates$ and the reduced model is $Phenotype \sim \beta_0 + \beta_1 SNP + \beta_2 SNP2 + covariates$. The difference between these two models is the interaction term, and thus, a significant likelihood ratio p-value indicates a significant effect of the interaction (β_3) above and beyond the additive effects from SNP1 (β_1) and SNP2 (β_2). If the result of interest is the effect of the interaction of the two SNPs when adjusting for the main effects of each SNP, it would be sufficient to consider the effect of the interaction term in the full model; however, when attempting to identify statistical epistasis, it is recommended to use the likelihood ratio p-value to identify significant SNP-SNP interactions (Hall *et al.*, 2017).

The interaction models above involve two SNPs, but how are the SNPs included in the model chosen? One option is to consider every pairwise combination of SNPs within a data set. This approach is not ideal, however, when dealing with large sets of genetic variants. The post-genome era has led to a consistent decline in sequencing cost and a commensurate explosion in high-throughput genotype data. Technologies such as exome sequencing and whole genome sequencing can identify millions to tens of millions of variants within a population of humans, lending the ability for researchers to study the associations of traits with genotypes at historically unprecedented depth and breadth. With this increase in genotyping power comes an increase in the number of potential interactions between genotypes, creating a steep multiple hypothesis testing burden (Eichler *et al.*, 2010; Maher, 2008; Manolio *et al.*, 2009). Because of this, exhaustive searches for significant interactions between multiple genetic loci within the context of trait association become incredibly difficult because associations of ever greater significance are needed to pass a multiple hypothesis testing correction with increasing numbers of genotyped loci. For instance, an exhaustive test of every two-way SNP-SNP combination from 500,000 SNPs will amount to 1×10^{11} pairwise SNP-SNP tests. If the Bonferroni correction at an alpha level of 0.05 is utilized as is common statistical practice, a model would need a p-value below 5×10^{-13} to be considered statistically significant when adjusting for the number of tests. With such a stringent significance threshold, it is likely that many true positives will go undiscovered with this approach. This problem is exponentially exacerbated when higher order genetic interactions are taken into account, for example the interaction between three loci instead of two (Greene *et al.*, 2010).

The rapid expanse of genotyping depth and breadth, accompanied by the exponentially increasing burden of multiple hypothesis testing, combine to create a situation in which exhaustive searches for significant interactions between genetic variants become untenable. Because of this, new techniques for searching for significant interactions only where they are likely to occur are motivated. These techniques fall into broad categories, including main effect filtering, knowledge-based searches, and machine learning approaches.

Logistically speaking, main effect filtering is a straightforward and simple method used to reduce the number of SNP-SNP models to test. It involves first testing SNPs for association with a trait of interest and choosing those exhibiting a main effect at a chosen significance threshold for subsequent SNP $\times$ SNP interaction. However, the major limitation of this method is that the SNPs chosen are only those that have a significant effect on the phenotype on their own, which precludes the possibility of identifying SNPs that only have an effect when combined with other variants (Ritchie, 2011).

Knowledge-based filtering offers an appealing alternative to main effect filtering, as the SNP-SNP pairs are chosen for interaction testing based on demonstrated biological relationships (Ma *et al.*, 2015; Ritchie, 2011, 2015; Sun *et al.*, 2014; Thomas *et al.*, 2009). Previous studies have shown success in applying prior knowledge to genetic interaction analyses for ovarian cancer (Kim *et al.*, 2014), multiple sclerosis (Bush *et al.*, 2011; Ritchie, 2009), HIV pharmacogenetics (Grady *et al.*, 2010), age-related cataract (Hall *et al.*, 2015; Pendergrass *et al.*, 2015), HDL cholesterol (Turner *et al.*, 2011; Ma *et al.*, 2015), and other lipid traits (De *et al.*, 2015). Knowledge-based searches for epistasis utilize external knowledge such as the organization of genetic variants into genes, biological pathways, and biophysical interaction networks to identify sets of genetic variants which are likely candidates for epistatic interactions without the need to evaluate or investigate all sets of genetic variants (Greene *et al.*, 2015; Moore *et al.*, 2012;

Table 1 Traditional encodings for genotypes in linear and multivariable linear regression analyses, including generalized linear models

<i>Genotype</i>	<i>AA</i>	<i>Aa</i>	<i>aa</i>
Additive encoding	0	1	2
Dominant encoding	0	1	1
Recessive encoding	0	0	1
Codominant encoding	0, 0	0, 1	1, 0

A biallelic locus with two possible alleles, here denoted as A and a, may be encoded in multiple manners intended to reflect the putative mechanism of action according to Mendel's laws. In this example, the non-reference allele (a) is considered dominant to the reference allele (A) for the purposes of defining dominance and recessivity. In the codominant encoding, two "dummy" or "one-hot" variables are used to denote the three genotype states.

Moore and White, 2006). As biological knowledge of the organization of genetic variants into genes, pathways, and networks increases, knowledge-guided design of epistasis search strategies is likely to improve. Importantly, advances in high-throughput biological interaction screens and functional genomics analyses are currently unlocking knowledge which can be expected to inform targeted searches for epistasis by discarding unlikely interactions, for example between genetic variants within genes that are not co-expressed. Conversely, interactions which are empirically likely based on biological knowledge may be prioritized for search, such as at protein-protein interaction domains between proteins which biophysically interact to transduce an intracellular signal.

In contrast to knowledge-based approaches, advances in machine learning techniques have led to development of algorithmic approaches to prioritize genetic variants which are likely to interact. Feature selection and feature construction methods aim to reduce the complexity of the search space, in this case representing combinations of genetic variants under study (Kira and Rendell, 1992a). The Multifactor Dimensionality Reduction (MDR) algorithm developed by Ritchie and Moore and modified by many others reduces the complexity of an epistasis search by constructing a new two-level feature from the distributions of the trait under study among the 9 possible two-locus genotype combinations between two biallelic variants (Ritchie *et al.*, 2001). Importantly, this new feature can be tested in linear and generalized linear models, as well as being appropriate for input into classifiers such as decision trees (Lou *et al.*, 2007; Moore and Andrews, 2015). MDR has been generalized to handle missing data, imbalanced classes, quantitative traits, permutation analysis, adjustment for covariates, and family pedigree information. Originally written in Java, MDR has recently been implemented in the scikit-learn framework for Python, a popular machine learning distribution (Pedregosa *et al.*, 2011).

In contrast to MDR, which is a feature construction method, feature selection methods can reduce the search space by identifying subsets of features themselves which are likely to interact without creating new features like that created by MDR (Kira and Rendell, 1992a). The Relief family of algorithms has seen application in epistasis discovery (Kira and Rendell, 1992b). Modifications of the Relief algorithm, including SURF, SURF*, multiSURF, and TURF can identify subsets of genetic variants which may be tested directly for epistasis (Greene *et al.*, 2009, 2010; Moore and White, 2007).

Beyond the issues relevant to reducing the multiple testing burden, a further challenge to identifying SNP models with epistatic action is the way SNPs are genetically encoded. Traditional encoding methods include additive, dominant, and recessive, and each make critical assumptions about a given SNP's biological action (Table 1). It is common for investigators to choose one encoding, most often additive. However, every SNP across the genome does not demonstrate the same genetic action. If a SNP is encoded under a different assumption than its true genetic action, this can lead to a reduction in power or inflation of false positive results. The traditional approach is inflexible and does not reflect the diversity known to exist in genetics. One approach to circumvent the bias in choosing a traditional encoding method is to use the codominant encoding when testing for interactions, which is a dummy encoding for the different genotype states. Still, further method development is needed to create encoding alternatives that are flexible to the diverse genetic action of SNPs.

Feature construction and feature selection methods are examples of machine learning methods which can provide information about likely interactions without incorporating expert knowledge, instead using the data itself. In contrast, knowledge-based methods leverage a growing base of orthogonal biological knowledge gleaned from increasingly high-throughput experimentation, including interaction screens. In the future, both machine learning methods and biological knowledge are likely to expand. Knowledge of pathways and biophysical interactions is steadily increasing, and software which can organize genetic variants under study into higher-order units such as genes, pathways, and networks will likely find increasing application in the search for epistasis. Commensurately, statistical advances in the form of novel association tests which can control type I and type II error and methods to assign appropriate genetic encodings offer to improve the quality of epistatic hypotheses generated in genome-wide studies, offering the power to quantify uncertainty in the search for gene-gene interactions (Wang *et al.*, 2016; Pattin *et al.*, 2009; Kooperberg and LeBlanc, 2008).

In sum, epistasis research faces a considerable challenge from the multiple hypothesis testing problem which has motivated the development and application of new approaches that aim to reduce the complexity of an exhaustive search through external knowledge of the search space or machine learning methods. It is reasonable to expect further developments in both areas in the future as biological knowledge accumulates. Simultaneously, advances in statistical and machine learning methodologies could lead to breakthroughs in epistasis discovery by utilizing patterns within data, including the most powerful ways in which to genetically encode SNPs. Equipped with both machine learning tools and external knowledge, the epistasis researcher of the future could circumvent the incredible complexity of all possible interactions between genotypes within a population and focus directly on discovery of biologically relevant interactions.

Beyond Epistasis: Investigating Additional Complexity in Precision Medicine

In this article, we have described the importance of exploring genetic interactions as well as the challenges surrounding these analyses and common methods to overcome those hurdles. For precision medicine to be a reality, though, investigating genetic interaction in combination with other types of complexity is a necessity. Here we will discuss the ways in which the environment, rare and structural variation, and multi-omics data are important features to consider for disease prediction in the context of epistasis.

The exposome, herein defined as all environmental exposures in an individual's life, has a major impact on health outcomes (Rappaport and Smith, 2010). A large portion of the complexities leading to common diseases are missed if the environment is not considered. Gene-gene-environment interaction models are especially difficult to test for the same multiple-testing reasons outlined previously. Currently, much of the work done in gene-environment interactions include candidate environmental exposures, but this prevents identification of gene interactions with novel exposures. Environment-wide association studies (EWAS) have successfully identified novel exposures associated with disease which can subsequently be used for gene-exposure interaction analysis (Patel *et al.*, 2010, 2013, 2014; Patel and Ioannidis, 2014; Tzoulaki *et al.*, 2012; Hall *et al.*, 2014, 2017). This approach decreases the search space to only include exposures identified through EWAS. Just as knowledge-based methods have been successful at identifying gene-gene interactions predictive of disease, database knowledge may be employed for integrating the exposome with epistatic models. The Human Metabolome Database (HMDB) (Wishart *et al.*, 2007), the Toxic Exposome Database (Wishart *et al.*, 2015), and the Comparative Toxicogenomics Database (CTD) (Davis *et al.*, 2017) are examples of databases with knowledge of gene-gene and gene-exposure relationships, which may be leveraged to build putative gene-gene-exposure models for testing. Understanding the connection between gene networks and the environment is an essential component to uncovering the etiology of disease.

Whether it be gene-gene or gene-environment interactions, the vast majority of studies have focused on common SNPs (Hall *et al.*, 2016a,b). However, rare variants and copy number variation (CNV) have demonstrated influence on many diseases, and methods that consider these types of data are therefore essential in discovering complex genetic and gene-environment interactions. Successful examples have been found for epistasis involving rare variation and between CNV and the environment (Kim *et al.*, 2017; Hall *et al.*, 2017; Albers *et al.*, 2012). Further, other -omics data such as from the transcriptome, proteome, and metabolome are important features in elucidating the biological impact of interactions at the gene level. There is need for development of methods to handle these types of data that have unique challenges such as limited power for detection and heterogeneity.

Finally, to investigate epistasis and gene-environment interactions with common and rare variants, CNVs, and multi-omics data, studies that generate multiple types of data (e.g., exposure, genotype, sequence, CNV, gene expression, metabolomic, proteomic) are critical. Costs associated with generating multiple data types on large sample sizes are limiting, however. Examples of studies with multiple data types available include the electronic MEDical Record and GENomics Network (eMERGE Network), the National Health and Nutrition Examination Surveys (NHANES), the Marshfield Personalized Medicine Research Project (PMRP), the Women's Health Initiative (WHI), and the Million Veterans Project (MVP).

As more data types become available for an increasing number of samples, the opportunity arises for improved understanding of biology and the complex processes at play in development of disease. Yet, further unmet methodological development needs will also emerge in finding the most appropriate ways to aggregate, quality control, integrate, and analyze multiple disparate data types. As such, there is immense opportunity to uncover the hidden etiology of disease as further data and methods become available.

Conclusions

To realize the goal of precision medicine, genetic interactions are an important part of modeling complexity that leads to common disease, and their consideration is essential. There are many examples of successful searches for epistasis in humans and non-human model systems. However, as data availability increases, so do the challenges of finding true genetic interactions amidst the noise. Many approaches offer promise in circumventing these hurdles. Still, to understand the mechanisms that lead to diseases, and leverage that knowledge in order make informed and individualized decisions about health care, epistasis must be considered in the context of the environment, rare variation, CNVs, and other types of inter-individual variation. For these reasons, multi-omics data must be incorporated in the search for epistasis. This is an exciting time for the field of biomedical informatics, as there is an abundance of available data and methods, and the further unmet needs for complex and integrative analyses using multiple data types leave ample room for exploration, innovation, and discovery.

Introduction

Inherited characteristics of an organism are encoded in a molecule called deoxyribonucleic acid (DNA), represented as a string of four-element code (ACGT). This molecule encodes the information required for the synthesis of all the proteins required for the functioning of cell that ultimately determines the phenotype of the organism. Variations introduced in this code introduces the changes in the organisms for natural selection to work on. The variable fitness level of organisms results in certain variations to be selected over time resulting in the incredibly different variety of viable organisms we see around. The genetic information in the DNA is transcribed into RNA by an enzyme called RNA polymerase. The RNA is then decoded into a ribosome, outside the nucleus, to produce a specific amino acid chain, or polypeptide. The polypeptide later folds into an active protein and performs its functions in the cell which then determines the phenotype of the cell and the organism ([Felix, 2016](#)).

The particular genetic encoding for an organism is called its *genotype* and the resulting physical characteristics is called its *phenotype*. In sexually reproducing organisms including humans, sexual recombination as well as mutations introduce variation in the *genotype* resulting in the variations in its *phenotype* enabling natural selection to select organisms with better fitness in their current environment. Small changes in the genotype space can have significant differences in the phenotypes resulting in the enormous diversity of organisms we see around. Our understanding of the genotype-phenotype relationship has helped us to understand the genetic cause of several diseases and have helped us to treat them with better efficacy ([Lehner, 2007](#)).

The DNA of an organism is typically packaged into several chromosomes in eukaryotic cells, exist in discrete chromosome territories. There is compelling evidence that suggest that each chromosome is comprised of many distinct chromatin domains, referred to variably as topological domains or topologically associating domains (TADs), that are hundreds of kilobases to several million bases in length. These chromatin domains are stable for many cell divisions, cell-type specific and demonstrated to play important roles in transcriptional regulation, DNA replication, and recombination. Additionally, regulatory DNA elements such as enhancers, silencers and insulators are embedded in chromosomes and they control gene expression during development and maintenance ([Pope et al., 2014](#)).

A significant step in our understanding of our genetic makeup happened when the first release of the human genome was announced by the Human Genome Project (HGP) in 2001. The Genome Reference Consortium (GRC) – an international, collaborative research program whose goal was the complete mapping and understanding of all the genes of a genome – facilitate the curation of genome assemblies for human, mouse or zebrafish ([Hudson, 2002](#)).

Once the genome sequence was established, the next task is to identify the functional elements in the genome. The ENCODE (Encyclopedia of DNA Elements) Consortium is an international collaboration of research groups funded by the National Human Genome Research Institute (NHGRI). The goal of ENCODE is to build a comprehensive parts list of functional elements in the human genome, including elements that act at the protein and RNA levels, and regulatory elements that control cells and circumstances in which a gene is active. The ENCODE consortium not only produces high-quality data, but also analyzes the data in an integrative fashion and provides tools to search and visualize them ([Consortium et al., 2007](#); [Consortium et al., 2012](#)).

The gene expression levels in a cell is also controlled using epigenetic mechanisms, defined as heritable alterations that are not encoded in DNA sequence. These modifications include mechanisms such as DNA methylation, histone modification, DNA accessibility and chromatin structure. The NIH Roadmap Epigenomics Mapping Consortium was launched with the goal of producing a public resource of human epigenomic data to catalyze basic biology and disease-oriented research. The Consortium leverages experimental pipelines built around next-generation sequencing technologies to map the epigenetic landscapes in primary ex vivo tissues selected to represent the normal counterparts of tissues and organ systems frequently involved in human disease ([Roadmap Epigenomics et al., 2015](#)).

The basic mechanisms involved in the translation of the molecular codes encoded in the genetic material to the proteins that do the functions are very similar in almost all organisms. Therefore, biologists can use other organisms to study the basic mechanisms to understand gene regulation. Organisms like mouse that are closer to humans in the evolutionary tree are used to model diseases in humans and have proved to be of significant advantage to our understanding of the genetic mechanisms of several diseases. The goal of the modENCODE consortium project is to provide the biological research community with a comprehensive encyclopedia of genomic functional elements in model organisms such as *C. elegans* and *D. melanogaster*, including the domains of gene structure, mRNA and ncRNA expression profiling, transcription factor binding sites, histone modifications and replacement, chromatin structure, DNA replication initiation and timing, and copy number variation ([Boley et al., 2014](#)).

The DNA sequence of any two individuals will be almost identical in the sense that the sequence will be matching in more than 99% of the genome. The 1% variations, however, may greatly affect an individual's disease risk. One of the significant DNA variation commonly studied is single nucleotide polymorphisms (SNPs). Sets of nearby SNPs on the same chromosome are inherited in blocks and is called a haplotype. The HapMap is a map of these haplotype blocks and the specific SNPs that identify

the haplotypes are called tag SNPs. The International HapMap Project is a partnership of scientists and funding agencies from Canada, China, Japan, Nigeria, the United Kingdom and the United States. This will make genome scan approaches to finding regions with genes that affect diseases much more efficient and comprehensive ([International HapMap, 2003](#)).

The high quality curated genomes made available by the GRC and the hapmap data from the consortium coupled with advanced sequencing technologies enable us to study the genomic variants associated with diseases or predisposition to certain diseases, develop or identify appropriate therapeutic strategies. Examples of such initiatives are the Alzheimer's Disease Sequencing Project (ADSP) to identify new genomic variants contributing to increased or reduced risk of developing Late-Onset Alzheimer's Disease (LOAD), the GoT2D consortia to understand the genetic architecture of type 2 diabetes, and The Cancer Genome Atlas (TCGA) – a collaboration between the National Cancer Institute (NCI) and the National Human Genome Research Institute (NHGRI) – has generated comprehensive, multi-dimensional maps of the key genomic changes in 33 types of cancer. Likewise, the International Cancer Genome consortium (ICGC) project generated a comprehensive description of genomic, transcriptomic and epigenomic changes in 50 different tumor types and/or subtypes which are of clinical and societal importance across the globe ([Devarakonda et al., 2013](#); [Cancer Genome Atlas Research et al., 2013](#); [Zhang et al., 2011](#)).

The Trans-Omics for Precision Medicine (TOPMed), is a program to generate scientific resources to enhance our understanding of fundamental biological processes that underlie heart, lung, blood and sleep disorders. The projects aim to integrate whole-genome sequencing data, metabolic profiles, protein levels and RNA expression data with molecular, behavioral, imaging, environmental, and clinical data to uncover factors that increase or decrease the risk of disease and develop more targeted and personalized treatments ([Auer et al., 2016](#)).

The identification of SNPs and other differences in an individual is complicated because of the difficulty in identifying the disease-causing alterations from the large number of SNPs observed in any individual. The 1000 Genomes Project was initiated to find most genetic variants with frequencies of at least 1% in the populations studied. Though the project started with the aim of profiling 1000 individuals from three populations, the final data set contains data for 2504 individuals from 26 populations. Low coverage and exome sequence data are present for all of these individuals, 24 individuals were also sequenced to high coverage for validation purposes. The variations present in apparently normal individuals helps to remove germline events and help to identify disease causing mutations ([Kuehn, 2008](#)).

Putting together, studying genome and variations within is crucial to understanding the evolution, diversity and diseases. Plethora of tools and techniques have been developed to elicit genomic structure, variations and their functional characterization. Hence, this article hi-lights the informatics of all important aspects of genomic study. However, before diving into genome informatics, we briefly discuss the evolution of genomic technologies in Section “Genomic Technologies in Genomic Studies”.

Genomic Technologies in Genomic Studies

The completion of the human genome project ([Lander et al., 2001](#)) (HGP) in 2004 heralded a new era in biomedical sciences and brought the world of genomics to the mainstream. The HGP costed about 500 million dollars and took about a decade to finish a human genome sequence. Over the next decade, the NIH championed new initiatives to foster technology development at a massive scale to be able to sequence the human genome at a fraction of the cost (\$1000) in a few hours. This provided a massive impetus that gave rise to whole slew of genomic technologies to not only generate the sequence of the genome but to also interrogate it for functional characterization.

Before the HGP, genomics was limited to site based analysis. No single technology existed that could provide a complete view of the genome. Light based microscopy techniques to detect signals from bio-markers that have been added to the genome have been around since the middle of the last century. However, these technologies either provided a very coarse view of the genome, or required the investigator to know precisely the location of the genome to query. In addition, these methods were tedious and expensive requiring hours of a highly skilled technician's time. These were followed by the advent of polymerase chain reaction (PCR) based techniques to interrogate the presence or absence of genomic segments. However once again these technologies were low throughput, time consuming and required prior knowledge of the genome of interest to design appropriate primers. To circumvent this problem, sequencing of the genome was adopted as a viable strategy to get de novo information on genomic regions of interest. The sequencing technologies evolved in 3 generations of advancements.

First generation sequencing technology: These methods were the first of the sequencing based methods – developed by Fred Sanger and colleagues in 1977 ([Sanger et al., 1977](#); [Prober et al., 1987](#)) that relied on incorporation of chain-terminating dideoxynucleotides during the DNA replication process. 'Sanger sequencing' was the mainstay of genomic interrogation technologies for close to 30 years and is even used currently for small projects and for validation experiments. The mean sequencing reads are ~700 bp in length. However, the throughput still remains severely inadequate compared to the more recent next generation sequencing methods described below.

With the successful completion of the HGP, most of which was achieved using Sanger sequencing methods, the genomic community focused on developing new platforms that would allow for cheaper, faster and less error prone DNA interrogation. Over the past decade, rapid research and development of genomic technologies, both microarray based and more critically sequencing based (“Next Generation Sequencing”) technologies have allowed us to get close to that aim, leading to the two generations of advanced hi-throughput sequencing technologies.

Second generation sequencing technologies: Next generation sequencing technologies were inspired by a new development called pyrosequencing ([Nyren et al., 1993](#)), pioneered by Pal Nyren and colleagues, and relied on luminescence produced and measured

during new DNA strand synthesis. Pyrosequencing is a sequencing by synthesis (SBS) based method that uses the DNA polymerase to construct nascent DNA strand using a template strand. Pyrosequencing was licensed by 454 Life Sciences (later acquired by Roche). They produced the first commercially available massively parallel sequencing technology (Ronaghi *et al.*, 1998). The 454 machines produced long contiguous reads in the range of 4–500 bps in millions of wells at the same time. However, the data from the 454 systems suffered from errors arising in nucleotide runs. In long nucleotide runs, the phospho-luminiscent based method had difficulties determining the precise number of nucleotides that were present (Ronaghi *et al.*, 1998).

At around the same time, Solexa and the SOLiD method of sequencing also gained momentum (Voelkerding *et al.*, 2009). Solexa (later acquired by Illumina) relied on the incorporation of dNTPs that are end terminated i.e., they can only incorporate one nucleotide at a time (Bentley *et al.*, 2008). Although this prevented the system from generating errors in the long nucleotide runs, it also limited the system to only generate about 35 basepairs at a time. Sequencing chemistry improvements and other developments allowed for read sizes of up to 250 basepairs to be sequenced (using the MiSeq system). In the most current state-of-the-art, the Illumina HiSeq method can produce about a 100 gigabases of nucleotide sequences in about 2 days for about a thousand dollars in price – there by realizing the goal of bringing low cost sequencing to the disease genomic studies and the clinic (Balasubramanian, 2011; Quail *et al.*, 2012).

Third generation sequencing technologies: There is considerable debate in the genomic community on how to set the various milestones that define a generational change between the continuous developments of sequencing technologies. We choose to define these milestones whenever there is a significant improvement in technology resulting in much better sequencing data.

One example of such a technology is the single molecule real time (SMRT) sequencing platform from Pacific Biosciences or PacBio (Quail *et al.*, 2012). The platform relies on polymerase based sequencing of single molecules of DNA in specially made wells known as zero-mode waveguides (Harris *et al.*, 2008). SMRT sequencing and its newest iterations (Sequel) produce read lengths in the range of 10–20 kb range (Rhoads and Au, 2015). The long reads (although plagued by a slightly higher error rate) provide much more sequence context than the short-read sequencing platforms and have enabled an unprecedented view of the genome (Nakano *et al.*, 2017). It allowed development of pipelines that can deliver de-novo assembled genomes of an individual in a few hours.

More recently nanopore based DNA sequencing technologies have come to the fore. While the idea of using channels (nanopores) to linearize DNA molecules and drive them through is not new, the Oxford Nanopore Minion machines have successfully commercialized the concept (Clarke *et al.*, 2009). The nanopore channel is capable of detecting the change in electric current as different nucleotides of the DNA molecule pass through the channel and thus can read the DNA sequence. The platform allows for potentially generating majority of DNA sequences in the same size range as the SMRT system, however the largest read lengths could top 100–200 kbp (Branton *et al.*, 2008).

There are several other genomic technologies that could be added to the gamut of third generation sequencing technologies, such as the BioNano Genomics' Irys platform and the Fluidigm C1 single cell system. Irys systems produced by Bio Nano Genomics are optical mapping based solution for interrogating large DNA molecules. It relies on DNA nicking enzymes that allow for a large DNA molecule to be tagged at certain known locations across the genome (Schwartz *et al.*, 1993). DNA molecule is then linearized and run through a sensitive system that can identify the nick sites. Identification of the genomic location requires prior knowledge of genome sequence and nicking sites.

The data and technologies greatly enhances our ability to understand the underlying genetics in the development and disease. However, we need to cross the hurdle of plethora of informatics problems. In the remainder of the article, we review the fundamental genome informatics problems and the respective methods based on Illumina sequencing data, long-read sequencing data and microarray data.

Genomic Structural Informatics

Eliciting genomic structure, identifying functional elements and variants that affect their function is critical to eliciting the genomic factors associated with cellular function, cellular state, cellular state transition, diversity, disease and ultimately devising appropriate treatment options. Plethora of informatics methods and procedures have been devised in conjunction with the technologies discussed in Section "Genomic Technologies in Genomic Studies" to elicit genomic structure and variation. This section outlines the informatics procedures to elicit linear as well as 3D organization of genome, identifying functional elements, and genomic variants that lead to diversity and disease.

Eliciting Linear Structure of Genome

A typical eukaryotic chromosome is at least millions of base-pair long while currently available sequencing technology can decode only hundreds to tens of thousands of base-pair in one stretch. Thus, in shotgun (short-read) sequencing approach, chromosomes are broken down in fragments and sequenced. The process of rejoining these fragments to build the linear structure of chromosomes is called assembly and the program that performs the merging of smaller fragments into larger contigs/scaffolds is called *assembler*. The assembly procedures are classified as (1) reference or template based assembly, and (2) *de novo assembly*. The reference based assembly uses genome assembly of a nearest species as starting point for assembly. It involves mapping the reads to the reference genome, resolving conflicts, restructuring reference genome based on the structural patterns observed in the genome to be assembled. On the other hand, *de novo* methods assemble the genome from scratch, discussed in detail below.

de novo assembly starts assembling the genome by connecting short sequence reads based on their similarity which gives rise to longer reads and eventually contigs and scaffolds. Long insert libraries and long reads, which can be generated using Illumina mate-pair and Pacific BioSciences (PacBio) technology (Shi *et al.*, 2016) respectively, have been used due to their capability to span larger repeats and provide better continuity to the assembly. *de novo* assembly algorithms can be divided primarily into 3 types: Greedy, Overlap-layout-consensus (OLC) and de Bruijn graph based algorithms (Miller *et al.*, 2010).

Greedy algorithms, which perform local optimization of an objective function, involve iteratively merging the reads based on sequence similarity until no more merging is feasible. The criterion for merging typically involves length and percentage identity of overlapping regions among the reads (Miller *et al.*, 2010). Greedy algorithms have been used effectively to assemble smaller genomes that are of repeat free. Popular greedy assemblers are Phrap (de la Bastide and McCombie, 2007), TIGR Assembler (Pop and Kosack, 2004), and CAP3 (Huang and Madan, 1999).

The OLC algorithms use a different overlap approach, which works in 3 steps: (1) The Overlap step involves all vs all pairwise overlap comparison among the reads and use it to create the overlap graph where nodes corresponds to reads and edges represents overlap between the reads; (2) The layout step involves analysis of graph to identify paths in which each node is being traversed just once (hamiltonian path); (3) The final step involves the consensus determination where reads overlapping the same base vote for the identity of that base (Miller *et al.*, 2010). Compared to the greedy algorithms, OLC approach can use long distance information and can be used for assembly of larger genomes with repeats. Some of the popular OLC assembler are ARACHNE (Batzoglou *et al.*, 2002), Celera Assembler (Myers *et al.*, 2000), Newbler (Margulies *et al.*, 2005) and Minimus (Sommer *et al.*, 2007).

Most popular category of *de novo* algorithms are *de Bruijn* based (k-mer graph) methods. They work in 2 steps: 1) reads are broken into k-mers (typically $k=25$) and de Bruijn graph is being constructed where each k-mer is a node and edges correspond to overlap of $k-1$ nucleotides between connected nodes. A simple de Bruijn graph of $k=3$ with 5 nodes is shown in the Fig. 1. For typical genomes, de Bruijn graph for carefully chosen k-mer size, most of neighboring nodes will be connected and distal connection (loop formation) will occur in the repeating region of the genomes only. The second step of the de Bruijn graph algorithm is to find an Eulerian path (a path in a graph where each edge is visited once) (Miller *et al.*, 2010). de Bruijn graph algorithms are fast and can be efficiently used for eukaryotic genomes' assemblies. Limitation includes sensitivity to parameter k and vulnerability to sequencing errors. Popular de Bruijn graph assemblers are Velvet (Zerbino and Birney, 2008), SOAPdenovo2 (Luo *et al.*, 2012), ABySS (Simpson *et al.*, 2009) and ALLPATHS-LG (Gnerre *et al.*, 2011).

The quality of *de novo* assembled genomes is tested using various metrics (Haiminen *et al.*, 2011): Contig N50/Scaffold N50, total number of known genes/transcripts found in the genome, the rate of discordant alignments (which quantifies mis-assembly) determined by mapping the paired end data back to the genome, completeness of the assembly detected by using CEGMA (Core Eukaryotic Genes Mapping Approach) (Parra *et al.*, 2007) which uses a set of 248 ultra-conserved CEGs conserved among *A. thaliana*, *C. elegans*, *D. melanogaster*, *H. sapiens*, *S. cerevisiae*, and *S. pombe*. One of the popular software to automatically detect the quality of the assembly is reapr (Recognition of Errors in Assemblies using Paired Reads) (Hunt *et al.*, 2013). It primarily measures the mis-assemblies and break incorrect scaffolds at mis-assembly points. More software packages for evaluation of quality of assembly can be found at "Relevant Websites section".

Putting together, a typical complete whole genome *de novo* assembly pipeline is shown in Fig. 2. It is based on sequencing of Illumina paired end, Illumina mate pair and low-coverage PacBio data. The steps of the assembly include QC of the raw data by NGS QC Toolkit (Patel and Jain, 2012), k-mer correction by corrector module of SOAPdenovo2, k-mer size estimation by KmerGenie (Chikhi and Medvedev, 2014), Assembly using SOAPdenovo2 (Luo *et al.*, 2012), gap closer using GapCloser module of SOAPdenovo2, evaluation & correction of assembly using reapr (Hunt *et al.*, 2013), and finally extending the contigs using low coverage ($\sim 5X$) data from PacBio using PBJelly (English *et al.*, 2012).

Inferring 3D Structure of Genome

DNA is tightly packaged in 3D space of the nucleus. Understanding the 3D genome architecture helps explain events such as promoter-enhancer interaction and disease development (Javierre *et al.*, 2016; Au-Yeung *et al.*, 2016; Martin *et al.*, 2015).

Identifying 3D genome interactions has been a popular approach to infer 3D structure of genome. Imaging technologies, such as microscopy, have enabled the identification of 3D genome interactions for specific predefined regions. On the other hand, chromatin conformation capture methods enabled a flexible platform to identify 3D genome interactions. For instance, 3C technology (Dekker *et al.*, 2002) enabled identification of the interactions between two predefined genomic loci. 4C (Zhao *et al.*, 2006) technology identifies 3D interactions between one locus and all other genomic loci. 5C (Dostie *et al.*, 2006) technology

Fig. 1 An example of a de Bruijn graph with $k=3$. It has one repeating k-mer thus instead of six it has only 5 nodes; blue line is showing the formation of loop pointing to the repeating k-mer (<http://www.homolog.us/Tutorials/index.php?p=2.1&s=1>).

Fig. 2 A schematic of de novo assembly pipeline using Illumina paired end, Illumina mate pair and low coverage PacBio data.

identifies interaction between two sets of predefined loci. Finally, the development of HiC (Lieberman-Aiden *et al.*, 2009) technology enabled the identification of 3D genome interaction at genome scale.

HiC technology generates a massive amount of data which introduced new computational challenges including speed and scalability for data processing, data normalization, and data visualization. To address speed and scalability challenges in processing HiC data, many specialized high-performance tools were developed, e.g., HiCPro (Servant *et al.*, 2015), HiFive (Sauria *et al.*, 2015), HiCBench (Lazaris *et al.*, 2017) and Juicer (Durand *et al.*, 2016a,b). In general, the output of these tools is a contact matrix quantifying the strength of interactions for all pairs of genomic bins. The resolution of the contact matrix increases with increasing sequencing depth.

HiC data normalization is a crucial step before proceeding into downstream data analysis. Sequencing process may introduce several biases innate in the HiC data. HiC data normalization methods fall into two main categories: explicit and implicit normalization. For explicit normalization, HiC data is normalized for each possible covariate (e.g., GC-content bias and sequencing depth bias) independently (Yaffe and Tanay, 2011). HiCNorm (Hu *et al.*, 2012) is an example of explicit HiC data normalization method. For implicit normalization, the main assumption is that any given genomic bin has an equal chance to interact with another bin. Most implicit normalization methods implement normalization using matrix balancing concept. Several implicit approaches have been developed including KR normalization (Rao *et al.*, 2014) and iterative correction and eigenvector decomposition (ICE) (Imakaev *et al.*, 2012) normalization.

As a typical genome browsers are not suitable to visualize 3D genome data, several groups developed specialized tools to visualize 3D genome data. These tools provide convenient ways to visualize 3D genome data including heatmaps, circular plots, and arc tracks. Examples of tools to visualize 3D genome are HiCBrowse (Paulsen *et al.*, 2014a), Juicebox (Durand *et al.*, 2016b), my5C (Lajoie *et al.*, 2009), 3D genome browser (see “Relevant Websites section”), and Epigenome browser (Zhou *et al.*, 2013).

Although HiC data is providing useful information, its coarse resolution limits its ability to map HiC interactions between functional elements (enhancer, promoter, insulators, etc) and the genome. To overcome HiC limitations, many technologies have been developed that focus on interactions that are related to genomic functional elements. These technologies include: chromatin interaction analysis by paired-end tag sequencing (ChIA-PET) (Fullwood *et al.*, 2009), and captureHiC (Martin *et al.*, 2015). ChIA-PET technology reports chromatin interactions that are mediated by specific DNA binding proteins such as CTCF or Pol II. For instance, interactions mediated by Pol II are more likely to contain enhancer-promoter interactions. On the other hand, captureHiC enriches interactions that involve active promoter regions to generate interaction maps between active promoters and the rest of the genome.

The informatics methods developed for HiC data analysis are no longer applicable to process ChIA-PET and captureHiC data. Thus, several methods were developed to process ChIA-PET data: ChIA-PET tool (Li *et al.*, 2010), ChIASig (Paulsen *et al.*, 2014b), and Mango (Phanstiel *et al.*, 2015) are a few examples. CHiCAGO (Cairns *et al.*, 2016) pipeline was developed to process captureHiC data.

Identifying Functional Elements in Genome

Immediate follow-up to genome assembly and 3D architecture prediction is to identify the functional elements such as genes, promoters and distant regulatory elements (e.g., protein binding elements, enhancers and insulators) to make sense of the genome.

Gene prediction approaches are mainly classified into two categories: (a) evidence-based, and (b) *ab initio* based (Picardi and Pesole, 2010). In the Evidence-based (Similarity or Homology-based) algorithms, the sequence of interest is searched against extrinsic homologous (shared evolutionary history) expression-sequence tags (ESTs), mRNA and protein sequences for complete or partial matches using exact algorithms like Smith-Watermann (Smith and Waterman, 1981) or approximate procedures like BLAST (Altschul *et al.*, 1990) and BLAT (Kent, 2002). A high sequence-similarity, for example, with a protein-product suggests that

the target sequence constitutes a protein-coding gene. Latest technologies like RNA-sequencing and Chip-sequencing data can also be exploited as external evidence for accurate gene prediction and validation (Pombo *et al.*, 2017; Hoff *et al.*, 2016; Sikora-Wohlfeld *et al.*, 2013). The extensive dependence on mRNA or protein sequences makes this approach an expensive and limited to known genes. In addition, gene prediction may be hampered by low quality sequences, frameshift mutations or horizontal gene transfers (in prokaryotes). In contrast, *Ab initio* methods rely on the intrinsic sequence content and pre-defined signatures in protein-coding genes i.e., the protein-coding genes are comprised of open reading frames (ORFs) which starts with an initiation codon (ATG) and ends with a triplet stop codon (TAA, TAG or TGA). In a double stranded DNA sequence, there can be six ORFs, three from forward direction and three from reverse (complimentary strand) direction that are always read from 5' to 3' direction. The average gene length in *E. coli*, *S. cerevisiae* and *H. Sapiens* is 317, 483 and 450 codons respectively (Brown, 2002). In general, prokaryotes' genomes contain only 6%–14% of non-coding DNA (Rogozin *et al.*, 2002) and their genes mainly contain continuous ORFs with well characterized promoter sequences, making ORF finding an effective way to identify genes. In contrast to prokaryotes' genomes, eukaryotes' genomes such as humans may contain up to 98% non-coding DNA (Elgar and Vavouri, 2008) and the gene structure is complex due to the presence of introns. They also contain complex promoter or regulatory regions comprised of variable length elements like CpG islands, making ORF finding challenging in eukaryotes. Moreover, eukaryotes may encounter selection of different exons from the same gene, producing multiple gene isoforms, further hampering the gene prediction. However, exons and introns in a gene can be traced using their specific sequence. The upstream sequence (5' end) at an exon-intron boundary is evolutionarily conserved and is mainly 5'-AG↓GTAAGT-3' where arrow indicates the exact breakpoint. The downstream sequence (3' end) at an exon-intron boundary is less evolutionary conserved comparatively and is 5'-PPPPPPNCAG↓-3' where P stands for Pyrimidine nucleotide i.e., Thymidine or Cytosine and N can be any nucleotide.

Gene regulation is combinatorial in nature and is achieved by the interaction of proteins binding to gene regulatory elements on the genome such as promoters, enhancers, insulators and transcription factor binding sites. Among these gene regulatory elements, promoters are the easiest to locate as they are mainly present upstream (5' end) of transcription start sites (TSS) and can be classified into core and proximal promoters. Core promoter region lies 100 base pairs around the TSS and acts as a binding site for general transcription factors (e.g., Pol II). On the other hand, proximal promoter is located few hundred bases upstream of TSS region. Prokaryotes generally contain two short consensus sequences in promoter, TATAAT (also called as Pribnow Box) and TTGACA at 10 and 35 upstream of TSS. On the contrary, eukaryotes promoter regions are more complex and are not well characterized. Many eukaryotic promoters contain a highly conserved TATA box (TATAAA) sequence within first 50 bases of TSS upstream region. Alternatively, some eukaryotic genes may also contain another promoter element called initiator (Kugel and Goodrich, 2017). Unlike TATA box, an initiator is comprised of a highly degenerate sequence 5'-PPA⁺N[T/A]⁺3PPP-3' where P is Pyrimidine (C or T) nucleotide, N can be any nucleotide, A⁺ is the transcription starting point and T/A is T or A nucleotide downstream (+3) of TSS. In contrast, the gene regulatory elements such as enhancers are located far away from the promoter or TSS region, up to few kilo bases or even mega bases in either direction (upstream or downstream) of the gene. The genomic approaches to identify these elements use chromatin immunoprecipitation (ChIP) based techniques like ChIP-Chip or ChIP-seq (Chen *et al.*, 2012; Heintzman *et al.*, 2007). Here, target protein is first cross-linked to cell's chromatin and then protein-DNA complexes are precipitated using protein-specific antibodies. The identity of DNA sequences, present in the protein-DNA complexes, are revealed by mapping them back to the genome and identifying enriched signals by peak finding algorithms such as MACS (Zhang *et al.*, 2008) and QUEST (Valouev *et al.*, 2008).

In eukaryotes, DNA is wrapped around a structure called nucleosome. Nucleosome's length is about 185 bp (Zhou *et al.*, 2011) and it is built from a family of proteins called histones. The combination of DNA and nucleosome is called chromatin. Histone protein tails may go through epigenetic post-transcriptional chemical modifications (Zhou *et al.*, 2011). These modifications include methylation, acetylation, and phosphorylation. Similar to the gene regulatory elements, ChIP-chip and ChIP-seq technologies are used in conjunction with bioinformatics methods (Ashoor *et al.*, 2013; Xu *et al.*, 2010) to identify chromatin modifications.

Chemical modifications of histone tails may correlate with gene expression; certain modifications (e.g., H3K27ac) correlate with increase in gene expression, while others (e.g., H3K27me3) correlate with decrease in gene expression. Many studies (Ernst and Kellis, 2012; Hoffman *et al.*, 2012, 2013; Hon *et al.*, 2008) used combinations of these modifications to demarcate functional regions in human and drosophila genomes. These methods use semi-supervised approaches to identify different patterns of several chromatin modifications and then annotate those patterns based on expert knowledge. Patterns help demarcate the genome into euchromatin and hetero-chromatin regions, identify gene regulatory elements such as enhancers and promoters. Moreover, specific chromatin modifications like H3k27ac, are used to identify super-enhancers in the genome (Pott and Lieb, 2015). Super-enhancers are defined as a set of closely localized enhancers, which are usually located near cell identity genes (Pott and Lieb, 2015). Super-enhancer detection programs work on constructing longer stitches of enhancer marks like H3K27ac. It then scores such longer stitches based on the abundance of mark reads to separate normal enhancers from super-enhancers. Examples of these programs are ROSE (Whyte *et al.*, 2013) and LILY (Boeva *et al.*, 2017) which is specialized to detect super-enhancers for cancer data.

Identifying Genomic Variants

The population diversity and disease are driven by the genomic variations present in the population and disease tissues. These variations include single nucleotide variants (SNVs) and structural variants (SVs). Identifying these variants help understand a variety of population traits as well as disease. Hi-throughput genomic technologies in combination with a variety of informatics

methods made their identification feasible at genome scale. However, a good quality control, alignment of the sequencing reads to the reference genome, and downstream processing are important steps for effective use of these technologies. A typical SNV calling workflows is given in **Fig. 3** and informatics of these steps is described below.

Quality Control: Sequencing technologies are not perfect and reads generated from every technology suffers from technical errors. Sequencing by synthesis method from Illumina have problem of deteriorating quality toward the 3' end of reads due to phasing (incomplete removal of 3' terminators and sequences in the cluster) (Kircher *et al.*, 2011). With increasing read length, more error accumulates which is problematic in signal detection and base calling. Moreover, if fragment length is shorter than the read length, added adaptors during the library-prep step occasionally get sequenced with the reads (Bolger *et al.*, 2014). This is problematic in the alignment the sequenced adaptors will appear as mismatches (due to non-reference bases). Thus removal of poor quality bases/adaptors is essential. The basic diagnostic involves generating the quality report using fastqc (See Relevant Websites Section), performing trimming/filtering using FASTQ/A Trimmer (see "Relevant Websites section") & trimmomatic (Bolger *et al.*, 2014), and adaptor removal using cut-adapt (Martin, 2011) & trimmomatic. High quality reads passing the trimming & filtering criterion will be used for downstream analysis.

Alignment: Alignment of the reads to the genome of interest follows quality control. Read alignment is a "pattern matching" problem. Aligners account for sequencing errors and align millions of reads to the genome at reasonable speed. There are various aligners available and can be broadly classified into two categories (Lindner and Friedel, 2012):

- A) Hash table based aligners use the seed and extend approach. To quickly perform the seeding, these algorithms store reads or reference genome as a hash table (Lindner and Friedel, 2012). They attempt to reduce the sequence search space without discarding the correct alignment candidates. Popular aligners in this category are Mosaik (Lee *et al.*, 2014), BFAST (Homer *et al.*, 2009), Novoalign (see "Relevant Websites section"), PASS (Campagna *et al.*, 2009) and SHRiMP2 (David *et al.*, 2011).
- B) FM-index based aligners work in two steps: first identify the exact matches and then build in-exact alignment from the exact matches. Various representations of suffix/prefix trie namely suffix tree, FM-index and enhanced suffix array are used to find exact matches (Li and Homer, 2010). In contrast to hash table based approach, alignment is needed only once for identical copies of substring in reference genome in FM-index based aligners. Popular alignment algorithms in this category are BWA (Li and Durbin, 2010), BOWTIE 2 (Langmead and Salzberg, 2012) and SOAP2 (Li *et al.*, 2009a).

Post Alignment Processing is an important step to increase accuracy of alignment and variant calling:

- A) Duplicate removal: Reads aligning to the same position could represent true alignments or PCR artifacts. It is recommended to remove the PCR duplicates prior to variant calling as duplicates from PCR could skew variant allele frequency estimates (Bao *et al.*, 2014). Popular methods for removing PCR duplicates include Picard, MarkDuplicates (see "Relevant Websites section") and samtools (rmdup) (Li *et al.*, 2009b). These tools identify duplicates based on their 5' alignment position and orientation with

Fig. 3 A schematic depicting typical variant calling workflow.

respect to the genome. The 3' position is not taken into account as trimming of 3' end of reads may result in reads of varying lengths.

- B) Realignment around indels: Various loci in a genome have indels (insertions and deletions) in the sample's genome with respect to reference genome. Alignment of reads with indels is problematic and often leads to inaccurate placement of reads with respect to reference as Indels cause nearby regions shifted. To circumvent this problem, GATK IndelRealigner (McKenna *et al.*, 2010) creates the list of problematic regions and perform the local realignment across these regions to create a consensus indel and thus minimizing the false SNP calls.
- C) Base Quality Score Recalibration (BQSR): Per base quality score emitted by the sequencing machine play important role in variant calling. However, quality values emitted by the sequencer are affected by systematic technical error which leads to over/under assessment of base quality in the data. BQSR step is designed to apply machine learning to model these errors and adjust the quality score for increased accuracy in variant calling. It works in 2 steps: 1) builds a model of covariation based on the data and set of known variation, covariation is analyzed for various features of the base such as machine cycle, quality score and dinucleotide context; and, 2) it adjusts the quality score in the data based on this recalibration model (McKenna *et al.*, 2010).

Variant calling: The primary challenge in variant calling is identifying/separating the real mutation signature from the noise embedded in the sequence data. The current popular algorithm from GATK suite for variant calling is GATK HaplotypeCaller (McKenna *et al.*, 2010) which works in four steps: 1) Active Region search, identifies the regions of genome containing the evidence of significant variation; 2) Identification of haplotypes by performing the assembly of Active Regions; 3) Perform pairwise alignment of reads with haplotype using PairHMM algorithm to determine the haplotype likelihoods based on read data; and, finally, 4) assign genotype to sample based on Bayes' rule for each candidate variant site. Other popular variant callers are FreeBayes (Garrison and Marth, 2012), VarScan2 (Koboldt *et al.*, 2012), SomaticSniper (Larson *et al.*, 2012) and MuTect2 (Cibulskis *et al.*, 2013).

Variant filtration: Errors are introduced during sequencing and bioinformatics steps, which can lead to misleading results. It is therefore necessary to assess various quality metrics to identify real variants. A few common metrics output by most variant callers are coverage and allele frequency. Filters based on these metrics would help get rid of low coverage and low allele frequency variants which are typically false positives. Similarly, variants in low-complexity regions (such as homopolymers and tandem repeats) or in regions with known assembly issues are likely to be errors and would need to be filtered out. Additionally, tool-specific filters would be useful to deduce the authenticity of a variant – for instance, the GATK variant callers (McKenna *et al.*, 2010; De Summa *et al.*, 2017) output information on the mapping quality, genotype quality, evidence of strand bias, position of variant allele along reads – which could be effective in identification and removal of erroneous variant calls.

Structural Variant (SV) calling: In addition to SNVs and microIndels, the structural variants (SVs) such as copy number variations (CNVs), Deletions, Insertions, Duplications, Inversions and Translocations are significant determinants of human genetic diversity (Genomes Project *et al.*, 2010; Mills *et al.*, 2011; Sudmant *et al.*, 2015). SVs can span in size from a few base pairs to chromosome scale, can cause diverse phenotypes and genomic diseases such as cancer. Over the next decade, we expect accurate detection of SVs would become regular practice at the clinic.

Traditional approach to the detection of SVs relied on karyotyping, PCR, FISH and microarray based approaches. However, these legacy approaches permit only a very coarse view of the SVs in the genome (Conrad *et al.*, 2010; Zhao *et al.*, 2013). With the advent of next generation sequencing technologies there has been an unprecedented growth in technological and analytical approaches for the identification of SVs. The massive amounts of sequence data generated from the first, second and third generation sequencing technologies has enabled us to detect SVs and resolve them down to the base pair level.

Currently there are three basic approaches to SV detection: (1) read-depth (RD); (2) split-read (SR) and (3) paired end (PR) (Fig. 4) (Medvedev *et al.*, 2009). RD aligns sequences against a reference genome and counts the depth to estimate the copy number of that particular genomic segment. Using alignment information, SR uses reads that have multiple alignments from different parts of the same read – as these could potentially be overlapping SV breakpoints. PR relies on the paired end nature of the sequencing data from the Illumina sequencing platform to find read-pairs that align abnormally to the reference genome and could have spanned of SV breakpoints.

However, each individual method has its own biases that prevent it from detecting the full spectrum of structural variations in the human genome. Therefore, there is a need for new and improved methods of detecting structural variations. One such method is fusorSV (Published at: <https://genomebiology.biomedcentral.com/articles/10.1186/s13059-018-1404-6T>, see "Relevant Websites section") which takes an ensemble approach to the problem. fusorSV is an open source framework that includes a data fusion model built using the 1000 genomes project as the truth set. The model is then used to integrate the output from eight most popular SV calling methods to come up with unified and comprehensive SV call set that maximizes discovery while reducing false positives. Plewczynski *et al.* (2016) provide a comprehensive overview of recent approaches to SV detection using sequence data from whole genome and whole exome sequencing platforms.

Genomic Functional Informatics

Annotating the function of genomics elements and variants is a critical step for meaningful interpretation of data. In this section, we review the *in silico* approaches to functional annotation of genomic elements and variants.

Fig. 4 Typical methods for SV detection (a) aCGH, (b) RD, (c) split read, and (d) paired-end. Adapted from Iskow, R.C., Gokcumen, O., Lee, C., 2012. Exploring the role of copy number variants in human adaptation. *Trends Genet.* 28 (6), 245–257.

Functional Analysis of Variants

The first step towards meaningful interpretation of variants and their functional impact on the genome is variant annotation. SNVs in coding regions can be characterized as transitions if they change a purine base to a purine base or a pyrimidine base to a pyrimidine base; or as transversions if they change a purine base to a pyrimidine base or vice-versa. Further, based on the type of amino-acid change, coding SNVs can be synonymous (no change in amino acid), missense (change in amino acid), or nonsense (introduction of a stop codon). Similarly, coding insertions and deletions (indels) can be classified as inframe if the size of the indel event is a multiple of three bases or frameshift if the size of the indel event is not a multiple of three bases and therefore shifts the reading frame.

The advent of projects such as 1000 Genomes Project (Kuehn, 2008), the Exome Aggregation Consortium (EXAC) (Lek *et al.*, 2016), Exome Sequencing Project (ESP) (See Relevant Websites Section), The Cancer Genome Atlas (TCGA) (Cancer Genome Atlas Research *et al.*, 2013) and others have provided rich catalogs of variants in a number of healthy and disease populations. Population level annotation helps in characterizing a variant as common or rare based on its frequency in different populations, which in turn is interpretation of the variant's impact on disease. In cancer studies, normal population allele frequencies are often used to characterize a variant as germline or somatic depending on whether its population allele frequency is above or below a certain threshold.

Variants can be further functionally characterized based on how conserved they are across different species, with the idea that functionally important variants are likely to be highly conserved. Conservation based scores provided by PhyloP (Pollard *et al.*, 2010), phastCons (Siepel *et al.*, 2005), GERP (Cooper *et al.*, 2005), SiPhy (Garber *et al.*, 2009), and others can be used to assess the evolutionary conservation of variants. Furthermore, prediction based scores such as SIFT (Ng and Henikoff, 2003), PolyPhen (Adzhubei *et al.*, 2013), FATHMM (Shihab *et al.*, 2013), MutationTaster (Schwarz *et al.*, 2010), etc can help evaluate the pathogenic nature of variants based on their the impact on the structure and/or function of the protein.

To understand the impact of variants on drug response and disease, they are annotated with information from clinical knowledge bases such as the JAX Clinical Knowledge Base (JAX CKB) (Patterson *et al.*, 2016), Clinical Interpretation of Variants in Cancer (CIVIC) (Griffith *et al.*, 2017), OncoKB (Chakravarty *et al.*, 2017), Pharmacogenomics Knowledgebase (PharmGKB) (Whirl-Carrillo *et al.*, 2012) amongst others. The clinical annotation of variants associates variants with therapies, diagnostic/prognostic information, and clinical trials, and thus helps assess the clinical relevance of variants.

Functional Analysis of Non-Coding Regulatory Elements

Functional analysis of non-coding regulatory elements is carried out by mapping their target genes and conducting functional analysis of the target genes using experimental or enrichment based *in silico* methods. As promoters were defined using a fixed short window around transcription start sites (TSSs) (−1 kb, +200 bp for example), mapping promoters to gene targets is

straightforward. In addition, recently, functional annotation of mammalian (FANTOM) consortium generated genome-wide and cell specific maps for promoters (Consortium *et al.*, 2014), transcribed enhancers (Andersson *et al.*, 2014) and other functional elements to genes including lncRNAs (Hon *et al.*, 2017) and miRNAs (de Rie *et al.*, 2017).

In the *in silico* approach, protein binding elements/sites and other distant functional elements are mapped to a nearest gene or all genes within a linear genomic window. The mapped genes are used to conduct enrichment analysis of Gene Ontologies, pathways, gene signature such as MSigDB. However, such approach has inherent bias due to non-uniform distribution of genes across the genome and widely varying gene lengths which leads to so called varying lengths of 'assignment domains' (Jair Zhou, 2012). The regulatory elements within an assignment domain of a gene are mapped to the gene. Assignment domain depends on the criterion used for mapping regulatory elements to genes. The bias is minimal if short windows (< 5 kb) are used with reference to TSS of genes. However, the bias was shown to be unacceptably high for other choice of reference (e.g., whole gene) or longer window sizes of the order of tens of kilobases. To circumvent this problem, GREAT (McLean *et al.*, 2010) and reFABS (Jair Zhou, 2012) were proposed for unbiased functional analysis. GREAT contrasts total length of assignment domains of the mapped genes to that of the genes in the functional category. Whereas, reFABS performs resampling based test to correct for the bias.

The target mapping can be more precise using experimental approaches that map interaction of the distant functional elements with promoters (e.g., enhancer-promoter interaction and TFBS-promoter interaction). 3D genome technologies such as HiC and ChIA-PET enable such precise mapping. Given the high resolution and targeted nature of ChIA-PET data, it is more suitable to discover promoter interactions compared to HiC data. Recently, more sophisticated methods were developed to identify enhancer-promoter interaction. For instance, promoter enhancer predictor (PEP) (Yang *et al.*, 2017) uses deep learning from sequence based features only to predict enhancer promoter interactions. Moreover, TargetFinder method (Whalen *et al.*, 2016), integrates information from 3D genome data, in particular HiC data, gene expression, epigenomic data (ChIP-seq and DNase-seq) to predict enhancer targets which can be used for the functional analysis of enhancers as described above.

Functional Analysis of Genes and Their Isoforms

Functional analysis of genes can involve determination of biochemical function, molecular regulation, interaction and expression of genes. Prediction of gene function mostly relies on sequence homology, domain annotation and interaction to functionally known proteins (Clark and Radivojac, 2011; Mostafavi *et al.*, 2008). The homology-based predictions rely on the hypothesis that significant sequence similarity of genes suggests the predicted functional similarity. Homology search for coding region of a gene against the non-redundant protein database, such as NCBI (National Center for Biotechnology Information), SwissProt, allows the initial determination of gene function. Existing methods such as, PSI-BLAST and HMMer (Bork *et al.*, 1998; Bork and Koonin, 1998; Koonin *et al.*, 1998) can determine subtle conservation of protein sequence, which can be used to assign function to an uncharacterized protein. Identifying common evolutionary origin of genes based on homology method can provide further insights into gene function. However, homology approach may have caveats in functional characterization of gene, as fewer amino acid differences can alter the protein conformation and so function, and mutations in genes although may retain the structure, but may confer distinct function (Sjolander, 2004). Gene ontology (Ashburner *et al.*, 2000) and UniProt Gene Ontology Annotation (UniProt-GOA) database (Barrell *et al.*, 2009) are the widely used resources to determine cellular component, molecular function and biological process.

Function prediction of RNA-isoforms: Alternative splicing (AS) is known to be the primary source of transcriptome and proteome diversity in eukaryotes. Functional characterization of specific isoforms and their relevance to cell growth, development and differentiation as well in disease has been reported. However, for most isoforms, the function annotations remain missing. Thus, the extent of functional diversity of alternate mRNA isoforms generated from AS is largely unknown.

Not all mRNA isoforms derived from AS are protein-coding. In addition, AS produces unstable mRNAs which are degraded by nonsense-mediated decay (NMD) machinery (Lykke-Andersen and Jensen, 2015). Transcriptome-wide analysis predicted that ~10% of mRNAs are NMD targets in human (Mendell *et al.*, 2004). Furthermore, some studies suggest that a large number of low abundant isoforms are the consequence of splicing noise, and therefore can be considered as non-functional isoforms (Melamud and Moul, 2009; Pickrell *et al.*, 2010). While, splicing error or noisy splicing is possible, the low abundance of the alternate isoforms can also be due to their high-turnover rate, for instance their recognition by NMD pathway and consequent degradation. Alternate isoforms can have tissue-specific expression and distinct functions (Flouriot *et al.*, 2000; Himeji *et al.*, 2002). Such variations in isoforms are difficult to capture based on sequence-based analysis.

Unlike annotating gene function, the isoform-specific functional annotation is limited by several constraints: (1) AS can lead to skipping of exons that encode protein domains (Liu and Altman, 2003; Resch *et al.*, 2004); (2) AS can cause disorder in amino acid sequence and structure, and thus functional change (Buljan *et al.*, 2012; Romero *et al.*, 2006); (3) AS resulting in a few amino acid changes in the open-reading frame can modulate the protein structure and function (Vogan *et al.*, 1996; Yan *et al.*, 2000); and, (4) mRNA isoforms can have opposite functions, for example, BCLX gene generate two isoforms, where one being pro-apoptotic and the other one being anti-apoptotic (Revil *et al.*, 2007). Most functional annotations are documented at gene levels (Barrell *et al.*, 2009) and genome-wide catalogue for isoform-specific function is still missing. However, methods are available that infer isoform functions based on domains and binding sites (Murvai *et al.*, 2001; Thibert *et al.*, 2005; Vacic *et al.*, 2010; Verspoor *et al.*, 2012). Several computational approaches have been applied to determine isoform-specific function (Eksi *et al.*, 2013; Jia *et al.*, 2010; Li *et al.*, 2014a,b; Tseng *et al.*, 2015). Another method modelled gene-isoform relationship as multiple-instance data

and developed a multiple instance-based label propagation method to predict functions. In addition, assessing isoform orthologues has been found to provide functional information (Jia *et al.*, 2010; Zambelli *et al.*, 2010). Further improvements in isoform function prediction method include integration of heterogeneous data: RNA-Seq, protein-sequence and structure, amino acid composition, protein isoform docking and post-translational modification (Li *et al.*, 2014a).

Functional Analysis of ncRNAs – miRNAs and lncRNAs

Computational functional analyses of microRNAs (miRNAs): Short RNAs are part of the broad family of non-coding RNAs, which perform many regulatory functions. In particular, miRNAs have major interest because of their activity in gene silencing through post-transcriptional repression (Bartel, 2009). Mature miRNAs are about 21–23 nucleotides (nt) in length (Winter *et al.*, 2009), single stranded molecules that bind to 3′ untranslated regions (3′ UTR) of their target mRNAs and regulate many biological processes, including cell differentiation (Bray *et al.*, 2009), organ development (Ambros, 2011). It has also been shown that miRNAs are involved in various diseases, such as cancer (Esquela-Kerscher and Slack, 2006; Bailey *et al.*, 2009) and cardiovascular disorders (Urbich *et al.*, 2008). The mRNA:miRNA interaction depends on a functional motif (2–7 nt) present in the 5′ end of the miRNA which is known as “seed” region (Lewis *et al.*, 2005). In most cases, these short sequences negatively influence the expression of miRNA target genes via translation repression or degradation.

Similar to distant functional elements, the function of miRNAs is also elicited by mapping miRNAs to their target genes, followed by functional analysis of target genes in an *in silico* approach. Numerous online and stand-alone bioinformatics tools have been developed to find miRNA target genes, see Table 1. These algorithms depend on so called *sequence to sequence base pairing*, i.e., complementarity of the base pairing (aka Watson-Crick base pairing) between the seed sequences of the miRNA and the 3′ UTR of the genes, to map miRNA target genes. Further improvement of the method is possible by investigating the nature of the evolutionary conservation of the miRNA and target sequences (Lewis *et al.*, 2005). Some methods predict secondary structure of the duplex to calculate thermodynamic stability of the mRNA:miRNA interaction (Rehmsmeier *et al.*, 2004; John *et al.*, 2004). Next, these predicted targets are used to determine biological processes (gene ontology (The Gene Ontology, 2017), disease ontology (Hillen *et al.*, 1991)) and pathways (Reactome (Fabregat *et al.*, 2016) and KEGG (Kanehisa *et al.*, 2017)) affected by the miRNAs and hence the function of miRNAs.

Computational functional analysis of long non-coding RNAs (lncRNAs): lncRNAs are RNA molecules with a length of more than 200 nucleotides (Perkel, 2013). lncRNAs typically do not encode proteins, certain lncRNAs were shown to have protein coding potential (Guo *et al.*, 2013) though. They are located throughout the genome (Derrien *et al.*, 2012) and exclusively localized in the nucleus (Vance and Ponting, 2014). However, a recent study also reported that it can be found in cytoplasm of the cell (Sun and Kraus, 2015). The lncRNAs are important epigenetic, post transcriptional and transcriptional regulators, and have a variety of functions in developmental, cellular, molecular and disease processes such as cancer (Sun and Kraus, 2015). Several bioinformatics resources are given in Table 2 to access the annotated and predicted lncRNAs with their function, disease association and expression analysis. Along with these resources, multiple tools have been developed to determine the functional properties of the lncRNAs. The tools use homology-based sequence similarity search such as BLASTn (Zhang *et al.*, 2008) and BLAT (Kent, 2002), alignment-based coding potential search (Kong *et al.*, 2007), alignment-free coding region search with CPAT (Wang *et al.*, 2013), motif-based analyses using HOMER (Heinz *et al.*, 2010) and MEME (Bailey *et al.*, 2009). Several R/ Bioconductor packages, for instance, ClusterProfiler (Yu *et al.*, 2012), GDCRNATools (Ruidong *et al.*, 2017) and WGCNA (Langfelder and Horvath, 2008) are also available to explore the gene enrichment, pathways and clustering-based network analyses for functional analysis of lncRNAs.

Population Genome Informatics

Over the last two decades, the availability of entire genomes of multiple species (Mouse Genome Sequencing *et al.*, 2002; International Chicken Genome Sequencing, 2004; International Human Genome Sequencing, 2004; Chimpanzee and Analysis, 2005; Rhesus Macaque Genome *et al.*, 2007) has enabled an in-depth investigation of different species at the molecular level.

Along with this, the advent of sophisticated sequence alignment algorithms (Schwartz *et al.*, 2003; Blanchette *et al.*, 2004) and the field of comparative genomics (Miller *et al.*, 2004) have contributed tremendously to a better understanding of evolution and function of genomes. Comparative genomics involves comparison of genomic DNA among different species to understand various genomic differences and similarities as well as the evolutionary relationship between them. This approach has been used by many scientists to study the pattern and rate variation of mutations across multiple species and it has been clearly demonstrated that mutation rates not only vary between species and organisms but also between different regions of a genome (Chiaromonte *et al.*, 2001; Hardison *et al.*, 2003; Ananda *et al.*, 2011). In fact, regions with high and low neutral substitution rates in the human genome have been shown to contain different functional classes of genes – neutral substitution hot spots are generally biased towards surface receptor and immune response genes while cold spots are biased towards regulatory genes (Chuang and Li, 2004). The knowledge of neutral mutation rate variation can also be valuable to the discovery of non-coding functional elements – specifically, to distinguish between functional conservation and low background neutral mutation rates. Functional prediction algorithms incorporating background rates demonstrate improved separation of functional and neutral sites (Siepel *et al.*, 2005; Taylor *et al.*, 2006; Tyekucheva *et al.*, 2008). Understanding mutation rate variation is also critical for elucidating how biochemical processes (e.g., replication, repair, recombination etc.) and errors in them drive mutagenesis.

The next generation sequencing (NGS) technologies, which have facilitated cost-effective sequencing of entire genomes, are being efficiently employed by projects such as the 1000 Genomes Project (Kuehn, 2008) the Exome Aggregation Consortium (EXAC) (Lek *et al.*, 2016), Exome Sequencing Project (ESP) (See Relevant Websites Section) and others to generate large population-scale resources. These large-scale population genomics projects provide rich comprehensive catalogs of genetic variation of various types (SNVs, indels, structural variants etc.) across human populations of different ancestries (African, European, East Asian, South Asian, South American etc.). They have helped understand the nature and extent of intra- and inter-population differences in genetic variation and have facilitated population-based interpretation of clinical findings, which is important to curtail misdiagnosis (Husten, 2016). Additionally, population genomics also helped identify candidate genes for different diseases based on the distribution of functional variants in them. Scores such as Residual Variance Intolerance Score (RVIS) (Petrovski *et al.*, 2013) and probability of loss of function intolerance (pLI) (Lek *et al.*, 2016) compare the observed genetic variation in a population based on the expected variation to identify genes that are more or less tolerant to functional genetic variation. Thus, they help identify genes under different selective constraints – for instance, genes with the highest tolerance for genetic variation are likely under positive selection, and those with the lowest tolerance under purifying selection. This information is pivotal to identification of candidate genes in a disease population.

Statistical genetics, based on the understanding laid above, makes use of statistical methods to study evolutionary processes that shape genetic variations, and to infer the effect of genetic variants on normal phenotypes and diseases. Besides analyzing the evolutionary constraints and patterns that help understand the genomic function, statistical genetics has proven to be a highly successful approach to identify genetic markers associated with phenotypes.

The early efforts to map disease genes were through linkage analysis in familial data (Laird and Lange, 2011). A marker gene and a disease susceptibility gene are in linkage if they are inherited together during the meiosis phase of sexual reproduction, namely the recombination fraction between them is smaller than one half. Parametric linkage analysis (Abecasis *et al.*, 2002) need to specify appropriate disease inheritance mode, disease allele frequency and penetrance, which may not be always obtainable. Non-parametric linkage analysis (Kruglyak *et al.*, 1996), which is based on identity-by-descent (IBD) sharing (Keith *et al.*, 2008), does not have such requirement, hence is more general. However, linkage analysis is most successful for Mendelian diseases (monogene for a disease), and much less powerful for complex diseases where polygenes dictate a disease. Since family data are hard to collect, association studies in unrelated subjects prevail for complex diseases.

Association analysis is based on linkage disequilibrium (LD) (Pritchard and Przeworski, 2001) among genetic variants. Two alleles of two variants are in linkage disequilibrium if their co-occurrence probability in a haplotype is larger than that when they are independent. r^2 is a LD coefficient for measuring such allelic associations (Pritchard and Przeworski, 2001). Disease variants,

which may not be typed in a study, can be tagged by its LD proxy variants. To achieve the same detection power, the sample size required in an association study which analyzes marker variants is proportion to the reciprocal of r^2 of that when disease causing variant is directly genotyped.

In order to tag most of the common SNPs, the number of typed SNPs in genome-wide association studies (GWAS) has increased from several hundred thousand to five million. Majority of the typed SNPs are common (minor allele frequency > 5%), and non-coding in GWAS. To increase SNP coverage, LD-based imputation methods (Marchini *et al.*, 2007; Marchini and Howie, 2010; Browning and Browning, 2009) for untyped SNPs were developed, which also made the meta-analysis among GWASs on different typing platforms feasible.

Exome array (Huyghe *et al.*, 2013; Liu *et al.*, 2017) for low frequency coding SNPs and exome sequencing (Kiezun *et al.*, 2012; Liu *et al.*, 2014) for rare coding SNPs are alternative ways to investigate roles of coding genetic variants. Two main approaches have been developed for rare variant association analysis which typically has low power. One is burden test (AL *et al.*, 2010) which sums up the counts of alleles of all rare variants in a gene region. Burden test is powerful when the majority of rare variants are functional and have the same effect direction. The other is SKAT-O (L. *et al.*, 2012), which calculates the weighted sum of test statistics for all variants in a gene region. SKAT-O is powerful when a large portion of the variants are neutral and/or have different effect directions.

In GWAS, the most common confounding factor is population structure, where population subgroups are associated with both disease and variant allele frequency, inducing the crude odds ratio different from the stratified odds ratio. The confounding effect of population structure can be adjusted by several ways. For example λ_{GC} correction (Devlin and Roeder, 1999), principal component correction (Price *et al.*, 2006), and linear or generalized linear mixed model (Chen *et al.*, 2016; Zhou and Stephens, 2012) correction.

Discussion

Genome informatics is critical to eliciting genomic structure and its relationship to individual and population phenotypes, including disease. Multiple aspects of genome informatics play important role in a modern genomic project. Though plethora of informatics methods have been developed for each aspect of genome analysis, none of them serve as single go-to tool. Hence, a combination of methods may need to be used for accurate analysis. In addition, while the emerging technologies offer opportunities to better understand the role of genome by generating more precise data, they pose brand new informatics challenges including developing new tools and integrative analysis.

"The genome sequence of an organism is an information resource unlike any that biologists have previously had access to. But the value of the genome is only as good as its annotation. It is the annotation that bridges the gap from the sequence to the biology of the organism." Lincoln Stein, 2001. *Nat. Rev. Genet.* 2(7), 493–503.

Introduction

The precise ordering of nucleotides and amino acids confer specific functional properties to biological sequences. Functional and structural features can then be understood as regions contained within those sequences, defined as segments delimited by an interval of positions, initial and terminal, on the coordinates axis provided by the sequence itself. In a wide sense, sequence annotation is defined by the procedures leading to determine the location and properties of these sequence features. Genomes are the organisms' blueprints, encoding for all the functional elements that lead to a fully developed life form. Therefore, genomes are complex and contain a mixture of features with different roles, which are interspersed with non-functional sequences under no evolutionary constraint. Genome annotation is the process of identifying any functional element along the DNA sequence of a genome, yet at initial stages often focuses on genes. The annotation gives meaning to the genome by providing the location and function of genes (protein coding or otherwise) and regulatory regions, which underlie the biology of living organisms. Completing the catalog of functional regions of the genome can facilitate further downstream analyses, as for instance the assessment of the effect of mutations caused by single nucleotide variants in individuals or populations. As it has been remarked since the start of the genomics era, raw genomes are thus of limited use to scientists and their annotation has become central to genome research.

Genome annotation itself has evolved over the years and it is possible to distinguish three, possibly four, major stages based on the techniques and data used. Each succeeding, yet overlapping, stage has refined previous annotations of the genome, characterized some of its previously unannotated parts, and provided novel insights into genome biology. The development in the mid 1990s of computational techniques to predict protein-coding genes, which span thousands of nucleotides in eukaryotes, marks the start of the efforts to provide genome-wide annotations. This first stage centered on the annotation of individual reference genomes (one per species), using a combination of the statistical properties of the sequences of the protein-coding genes themselves (to predict genes *ab initio*) and the similarity of mRNA and protein sequences to their genome of origin (to align known transcripts and proteins). Both approaches though rely on the existence of a set of already characterized genes, *a priori* knowledge based on experimental evidences, which will be used either as training set to build the models describing the genes species-specific signals and sequence content biases for subsequent computational predictions, or to be compared against other anonymous sequences to map their location based on similarity, thus annotating the genes in them (Fig. 1).

When the reference genomes of more species became available in the early and mid 2000s, they ushered in a comparative and second stage of genome annotation, where mRNA, protein and genome sequences from one species could be homologously aligned to annotate the genome of another. A third and regulatory stage of genome annotation was initiated in the mid and late 2000s, after genome-wide methods to profile DNA binding, conformation and alteration (*e.g.*, in their copy number) were introduced. Such genome-wide and multi-omics regulatory annotations have become standard in the last few years and short (in the tens or hundreds of nucleotides) regulatory elements are commonly annotated. Finally, genome annotation definitely moved away from one or few genomes per species in the late 2000s and early 2010s. This fourth and population stage of genome annotation, which uses hundreds if not thousands of genomes from the same species to annotate individual nucleotides, is where we find ourselves in the late 2010s. We discuss in some detail these different stages of genome annotation and how their increased resolution and inclusiveness of multi-omics approaches leads to more precise genome biology.

The *ab Initio* and Similarity Years

Ab initio gene prediction (also known as *de novo*) refers to the identification of protein-coding genes using the signals that define and characterize their gene structures along the genome. This is done without the aid of their encoded mRNAs and proteins. When the sequences of these mRNAs and proteins are sequenced they can be aligned to the genome to locate the genes that encode them. Thus, allowing the prediction of protein-coding genes by similarity. We discuss both approaches and the increased accuracy of similarity approaches over the *ab initio* ones.

Fig. 1 In order to annotate an anonymous sequence (query) we have two main approaches. The first approach, depicted on the left, it is to build models that, based on known sequences, summarize some property or bias characteristic of the functional elements being annotated, and then apply an algorithm to score these elements along the sequence, taking the optimal prediction as the one to annotate. The second approach uses the alignment against the query of the set of known sequences, retrieved either from the same (similarity search) or other species (homology search). Again, the optimal alignment is taken as the one to annotate the functional element. The coordinates – relative to the original sequence – define the location for each of the functional elements found in the anonymous genome, also known as the annotation set.

Ab Initio Gene Prediction

The structure of prokaryotic and eukaryotic genes is such that start (AUG) and stop (UAA/UAG/UGA) codons signal the initiation and termination steps of protein translation. These codons, together with some nucleotide context around them, define the coding DNA sequence (CDS) of the exon or exons in a gene. In eukaryote genomes, in particular, codons in exons along the CDS are not necessarily adjacent but often interrupted by introns of hundreds or thousands of nucleotides in length (Sharp, 2005). These breaks are defined, in most cases, by the canonical donor [AG|GTRAGT, where R=A or G] and acceptor [YTTYYYYYYNCAG|G, where Y=C or T and N=A, C, T or G] splice sites in mammalian genomes (Burset *et al.*, 2000; Abril *et al.*, 2005). Albeit GT-AG and the surrounding context defines a highly conserved motif, splicing is a complex biological process that tolerates small nuclear RNA variants in the spliceosome (Kyriakopoulou *et al.*, 2006), the RNA-protein complex that mediates the splicing process, and even non-canonical splice sites, such as those defined by the donor and acceptor pair AT-AC (Burset *et al.*, 2000; Patel and Steitz, 2003). Together with transcription initiation and termination sites, these signals have allowed the computational definition of prokaryotic and eukaryotic genes.

In addition, the genetic code is degenerate and the same amino acid can be encoded by different codons. These codons are synonymous and the frequency of their occurrence is known as codon usage or bias. Codon usage varies between species and between genes in a genome due to mutational biases and differences in the strength of natural selection on translational optimization (Plotkin and Kudla, 2011). Predating the sequencing of genomes there were tools that used codon bias to annotate expressed sequence tags (ESTs), fragments of mRNAs, which were even capable to correct frameshifts from sequencing errors like ESTSCAN (Iseli *et al.*, 1999). Thus, codon usage biases within the signals that define prokaryotic and eukaryotic genes can be used to computationally identify the CDS of genes along a particular species genome. Some of the first *ab initio* programs to predict genes this way did so in the short genomes of prokaryotes. For example, the seminal GENEMARK (Lukashin and Borodovsky, 1998) and GLIMMER (Delcher *et al.*, 1999) programs made use of Markov chains – a stochastic model describing a sequence of nucleotide-emitting states in which the probability of the next state only depends on the previous one – to capture the usage and dependence between successive nucleotides and codon positions, while defining the start and end of genes with models of the nucleotides around these signals (their sequence context). Interestingly, Markov chains of order-five, in which the probability of the next nucleotide depends on the five previous ones, work best in gene prediction as they also capture dependencies between consecutive amino acids in proteins (Durbin *et al.*, 1998). These models are used to score potential genes along the genome. The final prediction is then obtained using algorithms that find the optimal gene structure, that is, the combination of predicted exons that maximizes the score of the predicted genes. GENEMARK, for example, uses the Viterbi algorithm (Durbin *et al.*, 1998). This is a dynamic programming algorithm (Eddy, 2004a) – an optimization technique based on breaking down a problem into smaller ones and using them recursively to find the optimal solution – which, in a Hidden Markov Model (HMM) (Eddy, 2004b) – a statistical model following a Markov Chain process with hidden states that either emit nucleotides for coding or noncoding sequences – finds the best scoring gene structures. More recent developments include Prodigal (Hyatt *et al.*, 2010), which extends dynamic programming with a special set of rules to cope with overlapping genes while looking for the optimal gene structure prediction along the genome.

Hyatt *et al.* also established a reference annotation set to evaluate the accuracy of available prokaryotic gene-finders; a difficult task due to the lack of an experimentally verified translation start in many genes that changes the average length of genes, as well as the huge variability in GC content across prokaryota. The accuracy of gene prediction in prokaryotic genomes is generally high, with more than 95% of true protein coding genes being detected in most species (Hyatt *et al.*, 2010). Though the accuracy predicting the start of the gene is lower, usually around 80%. As a result, the 5' end (upstream) of prokaryotic genes is less likely to

be correct. In addition, prokaryotic gene prediction may still slightly overpredict the number of genes in a genome, with the resulting false positive genes being often short. It is however possible that some of these genes are indeed real. In any case, prokaryotic gene prediction has become remarkably accurate in the last two decades.

The identification of eukaryotic genes is, compared to their prokaryotic counterparts, more demanding due to their length (often in the hundreds of thousands of bases) and their split structure. Still, similar approaches to those in prokaryotes can be used. Early eukaryotic gene predictors included GENEID (Guigo *et al.*, 1992) and GENSCAN (Burge and Karlin, 1997). Both of these programs use Markov Chains of order five to assess codon usage and score coding exons as a combination of their coding bias and their start, end and splice sites signals; either in a rule-based (the GENEID Gene Model; (Guigo *et al.*, 1992)) or a generalized HMM (GHMM) framework for GENSCAN (Burge and Karlin, 1997). To cope with the combinatorial explosion of putative exons and predict the optimal gene structure along the genome dynamic programming was used (Burge and Karlin, 1997; Guigo, 1998).

The accuracy of such predictions is lower than in prokaryotic genomes (Table 1). An influential work on the assessment of gene prediction accuracy in eukaryotes (Berset and Guigo, 1996) established the ground metrics at the nucleotide, exon and gene levels, and provided one of the first reference gene test sets on this field. To begin with, there is in gene prediction a compromise between sensitivity (S_n in Table 1), the proportion of true coding nucleotides correctly predicted as such, and specificity (S_p in Table 1), the proportion of predicted coding nucleotides actually coding, so increasing one often decreases the other. At the nucleotide level this is not much of an issue, as fragments of most genes are predicted; yet missing the right start and end of an exon reduces the sensitivity and specificity of gene prediction at the exon level (Table 1). The accuracy for the overall gene is even lower due the difficulty in determining the right combination of exons along the genome. On the other hand, short genes encoding small proteins (Su *et al.*, 2013) are usually missed (missing exons, ME, in Table 1) as most genome annotation protocols apply a minimum length threshold, *i.e.*, of 100 amino acids, to reduce the number of falsely predicted genes (wrong exons, WE, in Table 1). These measures show that classic *ab initio* gene prediction programs identified no more than 80% of the true coding nucleotides while predicting as coding a large fraction of noncoding ones (Table 1). Also, a substantial fraction of coding exons had their boundaries mispredicted. Furthermore, around 40% of the predicted exons are completely wrong, a rather unreasonable figure. Still, *ab initio* gene prediction provided at the time a first set of annotations that could be later refined using comparative and/or experimental approaches (see below). To cope with annotation changes and multiple transcripts in a gene further accuracy measures have been proposed such as the Annotation Edit Distance, which quantifies changes to a gene annotation, and the Splice Complexity, which quantifies the complexity of alternative splicing in a gene (Eilbeck *et al.*, 2009). The terms recall and precision were later adopted to measure gene prediction accuracy. Recall is equivalent to the sensitivity measure described above, whereas precision is equivalent to specificity. Importantly, specificity or precision in the gene prediction field avoid the estimation of true negatives from incomplete genomes. Nowadays gene predictions are also compared with respect to the area under the curve in a receiver operating characteristics plot (known as AUC-ROC plot) (Powers, 2011).

The first large-scale assessment on gene-finding accuracy was performed over 2.4 megabases of the *Drosophila melanogaster* genome, which contained the *alcohol dehydrogenase* gene (*Adh*), in a collaborative experiment known as the Genome Annotation Assessment Project (GASP) (Reese *et al.*, 2000). This region was first annotated by human curators, with the raw sequence and a subset of the reference fly annotations later provided to the participants performing computational gene predictions. Similar assessments have subsequently been done in the worm (nGASP) (Coghlan *et al.*, 2008) and human genomes (EGASP and RGASP, see Figs. 2 and 3) (ENCODE Consortium, 2012; Guigo *et al.*, 2006).

Human curators have been invaluable in producing reference annotations for the above assessment experiments and in integrating the experimental evidence that validates (or refutes) individual gene predictions. For example, *D. melanogaster* was the first eukaryotic genome assembled from shotgun sequences (where DNA is broken up randomly) (Adams *et al.*, 2000) and Celera, the company sequencing it, organized an annotation jamboree with bioinformatics experts, protein specialists, and fruit fly biologists to functionally annotate it (Pennisi, 2000). Similar community annotation projects have since then become a standard for other genomes, among those it is worth citing the VERtebrate Genome Annotation database (VEGA, <http://vega.sanger.ac.uk>) maintained by the human and vertebrate analysis and annotation (HAVANA) group at the Wellcome Trust Sanger Institute (Harrow *et al.*, 2012), which also has defined guidelines to integrate gene annotations (Madupu *et al.*, 2010; Loveland *et al.*, 2012). To assist curators in the visualization and editing of gene annotations different tools have been created. First, to produce static maps of annotations along a genome sequence with GFF2PS (Abril and Guigo, 2000), GFF2APLOT (Abril *et al.*, 2003), and more recently CIRCOS (Krzywinski *et al.*, 2009). Later, tools to manually review gene predictions and integrate experimental evidence, such as APOLLO (Lewis *et al.*, 2002), the Integrative Genomics

Table 1 Accuracy of gene prediction programs on human chromosome 22

Program	Nucleotide			Exon				
	S_n	S_p	CC	S_n	S_p	$\frac{S_n+S_p}{2}$	ME	WE
<i>“ab initio” gene finding</i>								
GENEID	0.73	0.67	0.70	0.65	0.55	0.60	0.21	0.33
GENSCAN	0.79	0.53	0.64	0.68	0.41	0.55	0.15	0.48
<i>Comparative genomics approach</i>								
SGP2	0.75	0.73	0.73	0.66	0.58	0.62	0.19	0.28
TWINSKAN	0.72	0.67	0.69	0.69	0.59	0.64	0.18	0.29

Fig. 2 The assessment of the accuracy of gene predictions (or other functional features) is usually done in three steps. First, a set of well characterized genes is split into the training and the testing sequence sets. Second, the training set is used to estimate the species-specific parameters, such as the frequencies of the different codons in coding exons. Finally, the test set is used to predict genes with the computational approach under assessment. The sequence coordinates of the predicted genes are then compared against those of the known genes. Accuracy metrics, calculated at the nucleotide, exon and gene levels, are used to assess accuracy of the method and the reliability of the predictions. This assessment can be used later on either to estimate overall genome predictions reliability or to iterate through the train/test sets again in order to improve the software parameters (dashed lines).

Fig. 3 Sensitivity versus specificity scatterplots for the prediction of a number of defining signals in coding exons (CDS), on top row, and full-length exons, on bottom row, for the submitted predictions to RGASP. The accuracy metrics were computed over the genome sequences from three species: the human chromosomes three and four, the *Drosophila melanogaster* (fly) genome and the *Caenorhabditis elegans* (worm) genome. Each dot corresponds to a set of predictions made by one of each RGASP participant over one of the species sequences. Note the lower accuracy of predictions in the larger human genome as well as the difficulty to predict the untranslated part of exons due to missing the correct transcription start (TSS) and end (TES) sites in the three species.

Viewer (IGV) (Thorvaldsdottir et al., 2013) and the GALAXY server (Giardine et al., 2005) grew in importance. Over time, genome browsers providing access to databases storing the analyses from genome annotation pipelines have become the standard. These include GBrowse (Stein et al., 2002), the UCSC Genome Browser (Kent et al., 2002) and ENSEMBL (Hubbard et al., 2002; Aken et al., 2017), which are widely used today (Fig. 4).

Fig. 4 UCSC Genome Browser view of the human chromosome 17, focused on the sequence annotation around the *ACADVL* gene. Topmost annotation tracks show several gene/transcript structures obtained by different methods; mid tracks summarize the conservation score and the human sequence aligned to different vertebrate genomes; bottom tracks include sequence variants (OMIM and common variants), histone marks from the ENCODE project and transcript gene expression. The gene annotation tracks on top displays predictions from GENCODE, GENSCAN, SGP2, and AUGUSTUS, which can be compared with the current curated annotations from two reference sets, GENCODE and NCBI-RefSeq. From the aforementioned gene-finding programs, only AUGUSTUS predicts the three alternative spliced transcripts as it integrates experimental evidence, although it fails to predict some conserved exons detected by the other programs. Note that downstream *DVL2* gene was also detected by the gene-finders, but the upstream *DLG4* gene was missed.

Using mRNAs and Proteins

The sequencing of fragments (ESTs) or full-length mRNAs and proteins from the species whose genome is being annotated has been the main approach to increase the accuracy of *ab initio* gene annotation. Instead of relying on the statistical properties of the CDS and the signals that define them, the direct alignment of transcribed or translated sequences from a genome provides

experimental evidence to a gene structure. The alignment of such sequences to a naked genome has been computationally addressed yet again as a dynamic programming algorithm that takes into account the splice sites and exon/intron structure of eukaryotic genes. In particular, ESTs or full-length transcripts can be properly aligned to the genome using variations of the Smith-Waterman (Smith and Waterman, 1981; Gotoh, 1982) and Needleman-Wunsch (Needleman and Wunsch, 1970) algorithms, the classic local and global sequence alignment algorithms, respectively. This is the approach used by the pioneering EST_GENOME program (Mott, 1997). For the sake of speed, other approaches use the heuristic BLAST algorithm (Altschul *et al.*, 1990) to produce the starting alignments of coding exons in the genome, which are later recursively chained together to obtain the best gene structure. SIM4 (Florea *et al.*, 1998) and SPIDEY (Wheeler *et al.*, 2001) were examples of the latter. A more recent tool to align transcripts to a genomic sequence is EXONERATE (Slater and Birney, 2005), which provides (slower) exhaustive or (faster) heuristic approaches to align transcripts using different dynamic programming algorithms. On the other hand, spliced-alignment algorithms with proteins require the conceptual translation of the genomic sequence and finding the optimal alignment of a multi-exon structure to a related protein. PROCUSTES (Gelfand *et al.*, 1996) and GENEWISE (Birney and Durbin, 1997, 2000) are well-known examples, with the HMM-based GENEWISE at the core of the ENSEMBL gene annotation system (Curwen *et al.*, 2004; Aken *et al.*, 2016). The alignment of proteins to predict genes in large scale genomes can become extremely time- and space-demanding. This investment, however, is usually at the benefit of prediction accuracy. In this regard, the faster EXONERATE can also align proteins to DNA sequences and is also heavily used in the ENSEMBL pipeline.

In the last few years, the widespread use of next-generation sequencing technologies for genomes and transcriptomes (RNA sequencing, RNA-seq) and high-throughput mass spectrometry approaches for proteins have put the approaches above at the forefront of genome annotation. For example, the alignment of transcripts from RNA-seq experiments has allowed the comprehensive annotation of alternative splice forms of protein-coding genes. Humans, for example, produce on average four different protein-coding sequences per gene (ENCODE Consortium, 2012). Pseudogenes, which derived from functional genes through retrotransposition or duplication but have lost the original functions of their parental genes, are sometimes (about 10%) also transcribed (ENCODE Consortium, 2012). The high degree of conservation and similarity to functional genes of recent pseudogenes are significant enough to confound conventional gene prediction approaches (Zheng *et al.*, 2007). Other non-standard types of genes that have benefited from experimental evidence are fused genes, which combine part or all of the exons from transcripts of two collinear genes. In this way, they may contribute to the increase the protein repertoire in eukaryotes (Parra *et al.*, 2006). Similarly, trans-splicing, where the starting exons from one transcript are merged with exons from another transcript, far downstream or even located in another chromosome sequence, can be annotated using sequenced transcripts. Remarkably, up to 70% of the worm *Caenorhabditis elegans* mRNAs begin with the spliced leader sequence (SL, 22bp), which is not associated with the gene (Hastings, 2005).

Annotation of Non-Standard Protein Coding Genes

The identification of eukaryotic selenoprotein genes has challenged most computational gene prediction methods. The reason for this is the alternative use of the UGA codon, typically a termination signal, to code for selenocysteine (Chambers *et al.*, 1986; Zinoni *et al.*, 1986). The recoding of UGA confounds the computational identification of selenoprotein genes, whose exons containing a selenocysteine codon are truncated or skipped in their prediction. Selenocysteine, the 21st amino acid in the genetic code, is incorporated into selenoprotein with the help of an mRNA element, the selenocysteine insertion sequence (SECIS), located in the 3' untranslated region of selenoprotein genes (48,49). This RNA structure directs the incorporation of selenocysteine through the interaction with several trans-acting factors. Selenocysteine mediates the biological functions of selenium, an essential micronutrient whose deficiency is associated to infertility, preterm birth and serious children's disorders of the bone and heart (Rayman, 2000).

Efforts to identify selenoproteins were first directed to the computational prediction of the SECIS element in Expressed Sequence Tags (ESTs, sequenced mRNA fragments). Known SECIS elements were used to derive deterministic models of their secondary structures (Fig. 5) which, in turn, were used to scan and identify two novel selenoprotein genes (Kryukov *et al.*, 1999; Lescure *et al.*, 1999). Efforts to identify additional selenoprotein genes in eukaryotic genomes soon followed. The inclusion of UGA as a selenocysteine codon in the prediction of optimal gene structures along the genome, however, led to the prediction of many erroneous selenoprotein genes (false positives). The low specificity of selenoprotein gene prediction was due to the difficulty of using the typical codon usage characteristic of proteins to extend them beyond an in-frame termination codon (Castellano *et al.*, 2001). A solution to this problem was to use the prediction of SECIS elements along the genome to limit the number of exons with a TGA in-frame that are incorporated into the dynamic programming recursion used to predict optimal genes. Several new selenoproteins in different species were identified this way (Castellano *et al.*, 2001; Kryukov *et al.*, 2003; Castellano *et al.*, 2005). Another example of stop codon recoding is pyrrolysine, which is encoded by UAG but may not require a specific stem loop structure in the 3' untranslated region for translation (Zhang *et al.*, 2005).

The Comparative and Homology Years

The Zoo Blot is an experimental technique which uses Southern blot analysis to test the ability of a nucleic acid probe from one species to hybridize with DNA of a range of species. Zoo Blots were already used in the 1980s to characterize the protein coding

Fig. 5 (a) Schematic SECIS element (form 1) divided into structural units. Mostly invariant nucleotides are indicated. (b) Alignment of human and other mammalian glutathione peroxidase 1 SECIS sequences. Note the strong conservation among orthologous sequences. (c) Alignment of human and other non-mammalian glutathione peroxidase 1 SECIS sequences. Compared to the previous alignment, sequence conservation drops significantly.

regions of newly discovered genes (Monaco *et al.*, 1986; Katzav *et al.*, 1989). The rationale behind this approach was that protein coding regions will be conserved across species and would thus retain the capability to hybridize. Testing for hybridization of genomic probes to genomic libraries from many species will reveal the fragments likely to correspond to coding exons. As often happens, bioinformatics techniques based on sequence similarity replicate in the computer those experimental techniques based on the hybridization properties of nucleic acid molecules. In this regard, comparative gene prediction methods that rely on the fact that protein coding regions are generally more conserved during evolution than non-functional ones (Fig. 6), can be thought as a sort of electronic zoo blots. While phylogenetic footprinting – the phenomenon of the conservation of functional regions across species – has been used to discover, identify and characterize functional regions other than protein coding genes (Margulies *et al.*, 2003).

Essentially, there are two main classes of comparative approaches for gene identification: the comparison of the DNA query sequence with a target protein or mRNA sequence, or a database of such sequences (the computational equivalent of a Northern zoo blot), and the comparison of two or more genomic sequences. In both approaches query and target sequences may be from the same (as discussed above) or different species. If the latter, the selection of the target organism is not a negligible step; the organism should be chosen, when possible, at the phylogenetic distance maximizing the correlation between sequence conservation and coding function. Thus, allowing the inference of homology.

Using mRNAs and Proteins

The backbone of similarity-aided or similarity-based gene structure determination is constituted by those methods that rely on a comparison of the query sequence with protein, or mRNA sequences. Although mostly known as a database search program, BLASTX (Altschul *et al.*, 1990; Gish and States, 1993) illustrates the rationale behind this approach. With BLASTX a genomic query is translated into a set of amino acid sequences in the six possible frames and compared against a database of known protein sequences. The assumption is that those segments in the genomic query similar to database proteins are likely to correspond to homologous coding exons. A similar assumption is behind the comparison of the genomic query against a database of mRNA sequences (such as ESTs), using BLASTN (Altschul *et al.*, 1990), FASTA (Pearson and Lipman, 1988; Pearson, 2000), or similar programs. The National Center for Biotechnology Information GENBANK (Benson *et al.*, 2013) and UNIPROT (Bateman *et al.*, 2017), and their European and Asian counterparts, have been the main sources of nucleotide and protein sequences, respectively, for homology-based searches.

Fig. 6 Comparison of the orthologous genomic region of the acyl-Coenzyme A dehydrogenase very long chain (*ACADVL*) in human, mouse, and rat. The comparison was done at the amino acid level using the ungapped TBLASTX. Coding exons are shown as red boxes and non-coding ones (untranslated regions) are depicted in grey. Exons are projected to highlight their conservation (orange/grey ribbons). Note that introns are also conserved, albeit to a lesser extent than coding exons between human and any of the rodent genomes. The plot was obtained with GFF2APLOT.

Database search programs, however, are not dedicated gene prediction tools; they are not capable of automatically identifying start and stop codons or splice sites, the signals defining the exonic structure of the genes. Thus, after a database search and the identification of potential targets of homology, additional tools are required to define these structures. One approach is to use the top database match as target sequence and obtain a so-called spliced alignment between this and the genomic query. In such an alignment, large gaps – likely to correspond to introns – are only allowed at legal splice junctions. To calculate such spliced alignments between transcript and genomic sequences several programs we have already mentioned have been used: SIM4 (Florea *et al.*, 1998), EST_GENOME (Mott, 1997), SPIDEY (Wheelan *et al.*, 2001), and EXONERATE (Slater and Birney, 2005). Regarding the alignment of proteins of one species to another species genome, GENEWISE (Birney and Durbin, 1997, 2000) and EXONERATE (Slater and Birney, 2005) are used by ENSEMBL. In this direction, Meyer and Durbin (Meyer and Durbin, 2004) have developed the program PROJECTOR, which makes explicit use of the conservation of the exon-intron structure between two related genes. Because human and mouse orthologous genes show a remarkable conservation of their exonic structure, (Mouse Genome Sequencing Consortium, 2002), the PROJECTOR program outperforms GENEWISE predictions when human targets are used in mouse genomic sequences, and vice versa, in particular, when the conservation at the amino level is weak.

In an alternative approach, the results of a database search can be integrated *ad-hoc* into the framework of a typical *ab initio* gene prediction program. In essence, these methods promote candidate exons in the query sequence for which similar known coding sequences exist. Indeed, the score of the candidate exon – initially a function of the score of the splice (start, stop) sites and of the coding potential of the exon sequence – is increased as a function of the similarity between the candidate exon and the known coding sequences. In this way, candidate exons showing similarity to known coding sequences and thus likely orthologous, are promoted into the final gene prediction. In theory, this approach should produce predictions as accurate as pure *ab initio* programs when no similar target sequences exist, but more accurate ones (ideally, as accurate as those from splicing alignment tools) when such target sequences do exist. One example of this approach is the program GENOMESCAN (Yeh *et al.*, 2001), an extension of GENSCAN (Burge and Karlin, 1997) over which it reports increased accuracy. GRAILEXP (Xu *et al.*, 1997), CRASA (Chuang *et al.*, 2003) and AUGUSTUS (Stanke *et al.*, 2006a) are examples of methods using ESTs or mRNAs instead.

Using Whole-Genomes

With the increasing availability of the genome sequences for a wide range of eukaryotic organisms, whole genome sequence comparisons gained popularity as a mean of identifying protein coding genes. Under the assumption that regions conserved in genome sequence alignments will tend to correspond to coding exons from homologous genes, a number of programs were developed. The program EXOFISH (Crollius *et al.*, 2000) was one of the first such programs. Basically, it predicted human exons aided by the comparison of the human genome with sequences from *Tetraodon nigroviridis*, a puffer fish species (within Actinopterygii) that diverged about 400 Myr ago from the lineage later leading to humans. Latter developments followed notably different approaches.

In one such approach (Pedersen and Scharling, 2002; Blayo *et al.*, 2003), the problem was stated as a generalization of pairwise sequence alignment: given two genomic sequences coding for homologous genes, the goal was to obtain the predicted exonic structure in each sequence maximizing the score of the alignment of the resulting amino acid sequences. Both, (Blayo *et al.*, 2003)

and Pedersen and Scharling (Pedersen and Scharling, 2002) solved this problem through a complex extension of the classical dynamic programming algorithm for sequence alignment.

In a different approach, the programs SLAM (Alexandersson *et al.*, 2003) and DOUBLESCAN (Meyer and Durbin, 2002) combined sequence alignment pair HMMs (Durbin *et al.*, 1998), with gene prediction generalized HMMs (Burge and Karlin, 1997) into the so-called generalized pair HMMs. In these, gene prediction is not the result of the sequence alignment, as in the programs above, but both gene prediction and sequence alignment are obtained simultaneously.

A third class of programs adopted a more heuristic approach, and clearly separated gene prediction from sequence alignment. The programs ROSETTA (Batzoglou *et al.*, 2000), SGP1 (from Syntenic Gene Prediction, (Wiehe *et al.*, 2001)), and CEM (from the Conserved Exon Method, (Bafna and Huson, 2000)) are representative of this approach. All these programs start by aligning two syntenic sequences – understood here as sequences from different species, but containing homologous genes in a similar order –, and then predict gene structures in which the exons are compatible with the alignment.

Although similarity-based gene prediction with homologous genomic sequences produced high quality results (Miller, 2001), an obvious shortcoming was the need for two homologous sequences. Also, genes without a homologue in the partner sequence will escape detection. This is particularly problematic if species are compared at genomic regions where synteny is not preserved. Given only a single query sequence, it is therefore desirable to automatically search for homologous sequences or syntenic chromosome stretches in other species that are suited to similarity-based approaches. The programs TWINSCAN (Korf *et al.*, 2001) and SGP2 (Parra *et al.*, 2003) attempted to address this limitation. The approach in these programs was reminiscent of that used in GENOMESCAN (Yeh *et al.*, 2001). Essentially, the sequence from the query genome is compared against a collection of sequences from the target or informant genome – which can be a single homologous sequence to the query sequence, a whole assembled genome, or a collection of shotgun reads –, and the results of the comparison are used to modify accordingly the scores of the exons produced by *ab initio* gene predictors. In TWINSCAN, the query and target genome sequences are compared at the nucleotide level with BLASTN and the results serve to modify the underlying probability of the potential exons predicted by GENSCAN. In SGP2, the genome sequences are compared using TBLASTX (Altschul *et al.*, 1990), and the results used to modify the scores of the potential exons predicted by GENEID.

TWINSCAN, SGP2, and SLAM were successfully applied to the annotation of the mouse genome (Mouse Genome Sequencing, C, 2002), and helped to identify previously unconfirmed genes (Guigo *et al.*, 2003). Importantly, a number of studies consistently indicate that comparative gene finders improve over their *ab initio* counterparts (Parra *et al.*, 2003; Wu *et al.*, 2004). Indeed, in Table 1, we show that, when evaluated in human chromosome 22, TWINSCAN and SGP2 outperformed GENSCAN and GENEID, respectively. The exhaustive scrutiny to which the sequence of human chromosome 22 (Dunham *et al.*, 1999) was subjected through the Vertebrate Genome Annotation database project at the Wellcome Sanger Institute offers an excellent platform to obtain estimates of the accuracy of current gene finders.

Annotating a genome has required a complex craftsmanship from its inception, given the many different layers of annotations that have to be considered and therefore put together. Common to the tools and approaches described above is the first task of masking the repetitive sequences, often taxa-specific, that populate the genome; this step facilitates and speeds up the downstream analyses just by replacing the segments where the repeats are found by N's, a common nucleotide wildcard – meaning A or C or G or T-. RepeatMasker (Smit *et al.*, 2013-2015), has been the classical tool for this purpose, yet it has been described as sensitive but computationally costly when applied to large eukaryotic genomes (Bedell *et al.*, 2000). After repeat-masking, genome sequences are scanned for protein-coding and non-coding genes using different prediction tools while, simultaneously, homology-based searches and whole-genome alignments to other species are performed. The result are sets of annotations with varying degrees of supporting evidence that need to be integrated into one set of annotated genes, also known as the gene-build of a genome. Additional genome annotation layers result from high-throughput experimental approaches, such as RNA-seq and the transcriptional evidence it produces (which may be used on the gene-build itself), or the typing and resequencing experiments that sample sequence variation across populations (human or otherwise), and so on. Genes from the gene-build, and the proteins they encode, require these other annotation layers to assign them a molecular function, a process known as functional annotation. These functions rely on controlled vocabularies to describe them, for instance the Gene Ontology (GO) (Ashburner *et al.*, 2000; The Gene Ontology Consortium, 2017).

As the complexity of the annotation process increased due to the need to integrate new layers of information, guidelines and/or automatic or semiautomatic workflows to annotate novel genomes or to re-annotate existing ones (every time the assemblies are improved) were developed (Mudge and Harrow, 2016; Elsik *et al.*, 2014). For example, the NCBI prokaryotic (Tatusova *et al.*, 2016) and eukaryotic (Thibaud-Nissen *et al.*, 2016) pipelines, or EnSEMBL (Potter *et al.*, 2004), which rely on in-house protocols for large-scale genome annotation. In addition, gene-finding tools were wrapped into specialized genome annotation workflows. For instance, the Fgenesh (Salamov and Solovyev, 2000), SNAP+Exonerate, and GeneMark+ AUGUSTUS were integrated into the Fgenesh++ (Solovyev *et al.*, 2006), MAKER (Cantarel *et al.*, 2008), and BRAKER (Hoff *et al.*, 2016) annotation pipelines, respectively.

Comparative genomics can be also useful to assess the completeness of genome annotations. REFSEQ (Pruitt *et al.*, 2012) has been used as a reference annotation set for the annotation of novel gene-builds, but also to validate the completeness of genome assemblies. A set of 458 highly reliable core proteins, conserved across plants, fungi and mammals, was collected and integrated into a gene-finding validation pipeline known as CEGMA (Parra *et al.*, 2007). More recently, it has been superseded by a set of single-copy orthologs in the BUSCO pipeline (Simao *et al.*, 2015), which can be used to benchmark the completeness of both the annotation of genes and the genome assembly.

Annotation on Non-Standard Protein-Coding Genes

Comparative methods for gene prediction have been also useful to annotate selenoprotein genes. The fact that downstream of a recoded stop codon lies a real protein implies this region to have the typical pattern of sequence conservation among its protein homologues. At the least, to the extent of the conservation in the upstream protein sequence. Therefore, sequence conservation beyond a TGA codon in the genome strongly suggests selenocysteine coding function. It is then feasible to predict selenoprotein genes in two different species genomes, without information from their SECIS elements, and compare them to identify a pattern of symmetrical protein sequence conservation around a predicted selenocysteine codon. Application of this approach to the human and fugu genomes identified a new selenoprotein in this fish (Castellano *et al.*, 2004). More recently, selenoproteins have been annotated across eukaryotes, in a SECIS-independent manner, using alignment profiles derived from the known selenoprotein families (Mariotti and Guigo, 2010).

The RNA and Regulatory Years

The functional annotation of the regulatory and non-coding part of the genome has lagged behind the annotation of protein-coding genes. Systematic analysis of RNA genes and regulatory regions was made possible in the mid and late 2000s by a number of experimental approaches for the characterization of transcribed regions, transcription factor binding sites, DNA methylation sites and chromatin structure. The ENCODE project was an early adopter of these methods to systematically characterize the human genome, (2012 ENCODE Project Consortium). Among these, tiling arrays and RNA-seq have been important to understand the transcriptional landscape of the human genome, which is pervasively transcribed (Djebali *et al.*, 2012; Bertone *et al.*, 2004). This was perhaps not unexpected if one acknowledged the high initiation promiscuity of *Pol II*, the eukaryotic RNA polymerase complex (Struhl, 2007). In any case, transcription from regions where protein-coding genes or known RNA genes – such as ribosomal and transfer RNAs, small nuclear RNAs involved in splicing, microRNAs, short interfering RNAs, and a few others – have so far not been annotated, produced thousands of long noncoding RNAs with no obvious function. These unknown RNAs (Derrien *et al.*, 2012), which standard gene prediction programs cannot detect using codon bias measures, constitute a vast array of potential genes that do not encode for proteins (Kowalczyk *et al.*, 2012), albeit some may do (Ji *et al.*, 2015). While a few of these new RNAs have been shown to have functions (Nesterova *et al.*, 2001; Sleutels *et al.*, 2002), there is little functional evidence for the majority of them. Their transcription is often extremely low and they tend to have limited sequence or RNA structure conservation (Rivas *et al.*, 2017), raising the possibility that they are transcriptional noise. Indeed, between and within species analyses indicate that most of these RNA genes are not under strong evolutionary constraint (purifying selection) (Wiberg *et al.*, 2015). Alternatively, it could be their transcription itself rather than their sequence that is under selection. The functional annotation of RNA genes thus remains open and additional work is needed before this controversy is solved.

The high-throughput sequencing of transcriptomes and other experimental approaches has required the development of fast aligners like BWA (Li and Durbin, 2009) and Bowtie (Langmead and Salzberg, 2012), which can align millions of short sequences to a reference genome sequence. Specialized tools can integrate those alignments into predicted gene structures, such as AUGUSTUS (Stanke *et al.*, 2006b), mGENE (Schweikert *et al.*, 2009), or the Transomics pipeline (Solovyev *et al.*, 2006). Other tools, like SpliceGrapher (Rogers *et al.*, 2012), have been developed to refine the alignments of mapped sequences to predict “splicing graphs”, a representation of the splicing variants of a gene in which exons are shown as nodes that are connected by the intervening introns represented as edges. As discussed, obtaining simultaneously the genome and transcriptome of a species facilitates the task of gene annotation, by aligning the transcriptome sequences along the newly assembled genome, and provides an estimation of gene expression levels when translating the alignment coverage of read sequences into normalized counts (Mortazavi *et al.*, 2008). An extensive assessment of the sequence mappers (Engstrom *et al.*, 2013) and the gene-finders (Steijger *et al.*, 2013) was undertaken by the GENCODE consortium (Harrow *et al.*, 2012). Among the results obtained it is worth mentioning that 5'- and 3'-UTR exons were still difficult to predict (see Fig. 3) as well as the different exon combinations for splicing transcript isoforms, and that prediction accuracy correlated with the gene expression level, as highly expressed genes are often more abundant in the training sets. However, this is changing as single molecule sequencing methods, such as PacBio or ONT nanopore, produce long sequences recovering the full length splicing isoforms of a gene (Sharon *et al.*, 2013). Thus easing the task of protein-coding and non-coding mRNA genes annotation, even at single cell resolution (Byrne *et al.*, 2017).

Regulatory regions where proteins (*e.g.*, transcription factors) bind have been studied using chromatin immunoprecipitation followed by sequencing (ChIP-seq). Around 8% of the genome across different cell types is typically protein-bound with sequence-specific signals known to bind proteins being common in them. In addition, *DNase I* hypersensitivity has been used to identify those regions of the genome open to transcription. These regions can be bound by transcription factors and were found to be upstream of the predicted transcription start sites, coinciding with the regions defined by the ChIP-seq experiments. Methylation of cytosine, usually at CpG dinucleotides, is involved in the epigenetic regulation of gene expression, with promoter and gene methylation leading to repression and promotion of transcription, respectively. Levels of DNA methylation correlate with chromatin accessibility as defined by the *DNase I* hypersensitivity experiments. Interestingly, most variable regions in their methylation correspond to genes rather than their promoters.

One surprising result from the ENCODE project was the finding that the majority (about 80%) of the human genome participated in one or more of the experiments above (ENCODE Project Consortium, 2012), mostly in the RNA transcription

experiments discussed above. This was initially interpreted as providing evidence for a functional role to most of the human DNA sequence but low specificity of the assays used is a simpler explanation. These assays often do not distinguish between meaningful function – some molecular function that impacts fitness in the individual – and one that does not. As a result, having the majority of the genome performing important roles contrasts with the small fraction of it – probably 5%–10% – that has been shown to be under evolutionary constraint (Asthana *et al.*, 2007; Davydov *et al.*, 2010). It follows that some fraction of non-coding DNA is functional in the typical meaning of this word but that the majority of it – mostly transposable elements that make up about half of the human genome (Eddy, 2012) – is not (albeit being biochemically active in different experiments). Indeed, one of the common tasks in gene prediction is masking about half of the human genome for repeats and transposons using the venerable REPEATMASKER program.

The Population Years

The functional annotation of a species genome provides a reference to which additional genomes from the same species can be compared. Thousands of human exomes (protein-coding fraction of the genome) or genomes have now been sequenced (1k Genomes Project Consortium, 2012, 2015) and, in doing so, many differences have been found between them and their reference – *e.g.*, between four and five million nucleotide differences in each human genome –. These differences, which include single nucleotide variants, insertions and deletions, copy number variants and others, are often novel and unannotated, which each ensuing genome having more of them. These rare variants in humans, which are found in specific populations and at low frequency, are to a large the result of the recent growth of human populations (Keinan and Clark, 2012). Indeed, humans have accumulated in the last 5000–10,000 years an enormous number of rare variants, particularly in non-African populations. Protein-coding variants at low frequency are often slightly deleterious as measured by approaches that infer the probability of amino acid changes impacting the structure or function of proteins (Fu *et al.*, 2013). Programs like POLYPHEN (Adzhubei *et al.*, 2010) and SIFT (Kumar *et al.*, 2009), using amino acid conservation (within and between species) and different amino acid properties, annotate their deleteriousness across the genome. In addition, a few hundred variants disrupt the translation of proteins in a typical human genome. Non-coding variants in regulatory regions have also been annotated with regard to their deleteriousness using, for example, their conservation among species with PHASTCONS (Siepel *et al.*, 2005). It follows that the functional annotation of single nucleotide variants, particularly those that change (amino acid substitutions) or disrupt proteins (*e.g.*, changing splice sites or creating stop codons), are important to understand interindividual differences linked to diseases that are both rare and severe. Indeed, rare diseases, understood as those that occur in one out of 2000 individuals, have often a genetic basis and the annotation of the deleteriousness of the causal mutation(s) in single-gene disorders is the first step in their diagnosis and treatment.

Still, most of the genetic variation between individuals genomes of a species is shared among some (or most) of them. This common variation was described in a landmark study that provided not only a catalog of single nucleotide variants in humans but the genetic association among them (International HapMap Consortium, 2005). This association, known as linkage disequilibrium, reflects the coinheritance of sets of single nucleotide variants (haplotypes) and their functional annotation is needed to investigate, using genome-wide association studies, the hereditary factors involved in disease. This is important as each human genome has around 10,000 rare and common amino acid changes, a few hundred protein-disrupting ones and about 500,000 non-coding changes in regulatory regions (1k Genomes Project Consortium, 2015). Of these, about 2000 are linked through genome-wide studies with common disease whereas a few dozen are implicated with rare disease per genome. Today, thousands of mutations have been associated to common or rare disease in humans and their genome and functional annotation can be obtained from different databases, for example OMIM (<http://omim.org>), CLINVAR (Landrum *et al.*, 2016) and the NHGRI-EBI GWAS catalog (MacArthur *et al.*, 2017).

Conclusion

Genome annotation has come a long way since the first protein-coding genes were annotated using *ab initio* and later comparative approaches. Experimental evidence is now routinely integrated in the annotation of these genes and their multiple alternative splice forms. At the same time, promoters and smaller regulatory elements, as well as RNA genes (including controversial ones), are being annotated with a variety of experimental approaches genome-wide. Knowing the location of these coding and noncoding functional features has provided the framework to understand the role of sequence variants in health and disease, which remains largely undetermined. Still, since the early nineties, when the Human Genome Project was launched, our knowledge of genome biology has greatly improved. This is not only due to the ever increasing computational capabilities but also to novel discoveries in molecular biology from experimental methods with increased resolution and throughput, which has been harnessed in annotation consortiums like the ENCODE project. As a result, well annotated genomes like that of human, fly or mice, the result of years of intense human curation, as well as gold standards such REFSEQ or VEGA genes, provide reference annotations to other species.

This is important as the pace of sequencing new species genomes, transcriptomes, and environmental (metagenomics) samples is only accelerating given the ever decreasing cost of sequencing technologies. Thus, a shift towards more automated annotation pipelines is warranted to cope with the scale of the analyses in genome annotation. Automated annotation pipelines have room to

improve though, with gene-builds still having a significant impact in the downstream analyses. For example, on the variants found in a genome and their predicted functional consequences (Frankish *et al.*, 2015). This is due to the fact that most gene-finding tools return a single and often different set of optimal gene structures. This also poses a problem for overlapping genes, including those on different strands, nested genes, genes located within introns of other genes, non-standard gene structures, and genes with translation recoding like selenoprotein genes, as they are often not included in the optimal prediction of genes. Furthermore, most gene prediction tools do not consider frame shifts, RNA editing, and the impact of sequencing errors in the identification of gene structures. Still, some tools are capable to infer more than one alternative splicing isoform provided that there is some sort of experimental evidence, for example, from RNA-seq experiments. However, problems may appear when transcripts contain start or stop codons split by introns. Together with non-canonical splice-sites, these are some of the special cases that human curators solve in the final refinement steps of genome annotation when all sort of evidences are integrated. Many of aforementioned issues will be overcome by the use of single molecule sequencing technologies, which make possible to map the full length of individual protein-coding and non-coding transcript isoforms. In combination with single cell gene expression experiments, it will be finally feasible to produce gene-builds and their corresponding functional annotation at the single molecule and cell resolution, an astounding promise just two decades ago.

Biographical Sketch

Josep F. Abril, PhD Associate Professor at the Department of Genetics, Microbiology and Statistics of the Universitat de Barcelona. He earned his Bachelor's degree in Biology from the Universitat de Barcelona, and his PhD in Bioinformatics from the Universitat Pompeu Fabra in Barcelona. His research focuses on the computational analysis of sequences and their annotated features. He has worked on a variety of genomic and transcriptomic projects, but also on the functional characterization of proteins, and on different areas in computational biology. These include the development of protocols for the assembly and annotation of genomes, the use of comparative genomics methods, the analysis of gene expression, the modeling of splice sites and exonic structure of eukaryotic genes, the visualization of whole-genome annotations – this includes the human genome map published in *Science* in 2001 – the integration of expression and variation data into interaction networks, as well as the characterization of viral samples from metagenomic experiments. His organisms of interest are planarians, flies, and humans, not necessarily in that order, although he contributed to the annotation of other species too. Finally, he has been involved in the organization and analysis of three of the most relevant gene-prediction accuracy assessments in computational gene prediction, namely GASP in the *Drosophila* genome and EGASP and RGASP in the human one.

Sergi Castellano, PhD Associate Professor at the Genetics and Genomics Medicine Programme at University College London. He received his Bachelor's degree in Biology from the Universitat de Barcelona, and his PhD in Bioinformatics from the Universitat Pompeu Fabra, also in Barcelona. His group works on understanding the role of essential micronutrients, with particular emphasis on selenium, in the adaptation of human metabolism to the different environments encountered by archaic and modern humans. Much of his early work focused on the identification and characterization of functional elements in eukaryotic genomes, primarily selenium-containing genes, which are missannotated in standard databases. At the University of Hawaii, he developed the first database, SELENODB, with correct annotations for selenium-containing genes across animal genomes. Later, while at Cornell University and Howard Hughes Medical Institute, he used population genetics and molecular evolution approaches to study the evolution of the use of selenocysteine, the selenium-containing amino acid, compared to cysteine in proteins. More recently, at Max Planck in Germany, his group contributed to the population genetics analysis of Neandertals as it relates to their coding variation and their first encounters – as early as 100,000 years ago – with modern humans. His group is currently working on the role of micronutrient deficiencies in common and rare disease.

Repeat in Genomes: How and Why You Should Consider Them in Genome Analyses?

Bp	Base pairs	NGS	Next Generation Sequencing
ChIP	Chromatin Immuno Precipitation	SINE	Short Interspersed Nuclear Elements
Kb	Kilo base pairs	SSA	Sequence self-alignment
LINE	Long Interspersed Nuclear Elements	SSR	Simple Sequence Repeat
MITes	Miniature Inverted-repeat Transposable Elements	STR	Short Tandem Repeats
		TEs	Transposable Elements
		TIR	Terminal inverted repeat

Introduction

Repeats: A Large Bestiary Grouping Very Different Sequences

Although the genome size has been shown in prokaryotes to largely correlate to its complexity, i.e. the number of genes, it is not the case in eukaryotes. This observation, often referred to as the C-value paradox, can be partly explained by the fact that coding genes in eukaryotic genomes may represent only a tiny fraction of the total genome (Elliott and Gregory, 2015). In fact, it has been shown that the proportion of non-coding sequences in genomes may be particularly huge. For example, the coding genes in the human genome only represent 2% (Lander et al., 2001). A large proportion of the non-genic sequences are represented by repeats. In a genome, repeats correspond to non-coding sequences present in several occurrences. Two main categories of repeats are described, the tandem repeats and the interspersed repeats (Fig. 1). Another type of repeats exists in a genome which correspond to segmental duplications, which are very large nearly identical sequences (from 1 to 400 kb) often referred to as “low-copy repeats” (Sharp et al., 2005).

The tandem repeats correspond to sequences having a size from few to hundred of base pairs (bp) occurring in tandem and over several hundred of kilo base pairs (kb), which characterized them as “highly repeated sequences”. We can distinguish among this category the Simple Sequence Repeats (SSR) also called Short Tandem Repeats (STR) or microsatellites, which are a short tract of adjacent DNA motifs (around 1 to 13 bp) and the minisatellites which are longer (around 14 to 500 bp), both types being repeated several times (from 5 to 50 times for example). This type of repeats usually occurs at particular regions of the chromosomes corresponding to the telomeres and centromeres, but they also can be found throughout the genome, especially in regulatory and coding regions of genes (Richard et al., 2008).

The interspersed repeats stand for sequences that are more often known under the name transposable elements (TEs). These particular sequences were discovered during the 1950s by Barbara McClintock (1950). TEs have the particularity to be able to move from one position to another along the chromosomes since the majority of them encode all the proteins necessary for their

Fig. 1 Schematic representation of the different types of repeats.

transposition. Various types exist, according to structural features, the transposition intermediate (RNA or DNA), and their evolutionary origin (Wicker *et al.*, 2007; Kapitonov and Jurka, 2008). Retrotransposons use an RNA intermediate and form the class I, in which are found the Long Terminal Repeat (LTR)-retrotransposons (endogenous retrovirus-like mobile elements) which possess from two to three open reading frames (gag, pol, and env) and the non-LTR retrotransposons grouping the LINE and the SINE elements (standing for Long and Short Interspersed Nuclear Elements respectively). DNA transposons use a DNA intermediate and form the class II. They possess short terminal inverted repeats (TIRs) at their extremities surrounding one open reading frame coding for a transposase. Different types of DNA transposons have been classified mainly on the basis of the presence or absence of a catalytic site in the protein responsible for their transposition. A specific category of non-autonomous elements among the DNA transposons exist, the Miniature Inverted-repeat Transposable Elements (MITEs) that may be particularly numerous in some genomes. Depending on the organism, the proportion of TEs can be highly variable and at times very large. For example, their proportion in genomes represent 3% in yeast (Kim *et al.*, 1998), 15% in *Drosophila* (Dowsett and Young, 1982), 45% in human and in the mouse (Lander *et al.*, 2001; Waterston *et al.*, 2002), and more than 80% in maize (Schnable *et al.*, 2009).

“From Junk to Funk”: The Importance of Repeats in the Genome Functioning and Its Evolution

Repeats, and more particularly TEs, have long been considered as selfish and unnecessary components of the genomes. However, since the work of Britten and Davidson (1969) where TEs were for the first time considered as potentially playing a role in the gene regulation, numerous examples have flourished allowing to show the genuine importance of such sequences in genomes (Biemont, 2010). By their ability to move and because they are repeated, TEs can promote various types of mutations, which are expected to be mostly deleterious when affecting functional regions. When TE insertions occur in or near protein-coding genes, they can result in coding sequence modification or alteration of their splicing or polyadenylation patterns, therefore disrupting the protein coding capacity of the gene. Moreover, because TEs possess their own regulatory sequences, they can alter the normal expression pattern of neighboring genes while inserted in an intergenic region (Kidwell and Lisch, 2000; Biémont and Vieira, 2006). The possibility of homologous recombination between copies can also promote illegitimate recombinations, chromosome breakages, deletions and genome rearrangements (Kidwell and Lisch, 2000; Biémont and Vieira, 2006). In human, 0.3% of TE insertions have been suggested for causing disease (Belancio *et al.*, 2008) and approximately 96 new transposition events were directly linked to single-gene diseases (Hancks and Kazazian, 2012). For example, the *Alport* syndrome has been shown to be due to a TE mediated rearrangement resulting in the partial deletion and fusion of two genes (Segal *et al.*, 1999). More specific to cancer, the disruption of the APC gene caused by the TE insertion is involved in a colon cancer (Miki *et al.*, 1992). Despite the deleterious effects they may have, TEs have also been associated with useful adaptation for their host genome. For example, the antigen receptor gene assembly by V(D)J recombination in vertebrates is performed by genes that originated from a DNA transposon (Agrawal *et al.*, 1998). TE insertions near specific genes confer resistance to insecticide for some insects (Rostant *et al.*, 2012). These examples make TEs to be now considered as major players in genome evolution due to the genetic and epigenetic diversity they can promote (Biémont and Vieira, 2006). Similarly, tandem repeats have been found to play a fundamental role in the organization of the genome (Dumbovic *et al.*, 2017). For example, changes in mini- and micro-satellites correlate with various diseases but are also associated with gene regulation (Dumbovic *et al.*, 2017).

In addition to the fundamental biological role repeats have in genomes, in the current big sequencing era, they also represent a technical challenge that may complicate the task of genome assembly and sequence alignment. For example, the presence of repeats in a genome is the major source of genome mis-assemblies via rearrangement assembly errors and collapsed repeats but also in the assignment of splicing events and gene expression estimate in transcriptome analyses (Treangen and Salzberg, 2011). Since simply ignoring these sequences is not an issue in genomics, it is important to be able to identify them.

Bioinformatic Approaches to Identify, Annotate and Analyze Repeats in Genomes

Since several decades, numerous bioinformatics tools have been developed to allow a better identifications of repeats in genome assemblies (Lerat, 2010; Modolo and Lerat, 2013; Saha *et al.*, 2008; Bergman and Quesneville, 2007). New tools continue to arise regularly to follow the progress in sequencing technology in particular, but also to response to specific biological questions. According to the type of data on which they can work and the biological question, the different tools can be separated into various categories (Table 1).

Detection of Repeats in Assembled Genomes

Diverse methods exist to allow the detection and annotation of repeats in assembled genomes. These methods depend on the type of repeats and on the knowledge we have concerning their content inside the organism under investigation. Repeat annotation is a particularly complex computing problem due to the nature of the sequences, especially in the case of the TEs. Indeed, the TEs are not always exact repeats since a large divergence among copies can occur and TEs also can be found in the genome inserted inside each others (nested insertions). The detection of TEs has led to the development of a large number of different tools that fall in different categories according to the approach they use. Two main types of approaches exist: the library- or signature-based methods and the *ab initio* methods.

Table 1 Non-exhaustive list of tools to identify and analyze repeats

Program name	Type of repeats	Input data	Approach	References	Websites
Tandem Repeat Finder	Tandem repeat	Assembled genome	Identification	Benson (1999)	https://tandem.bu.edu/trf/trf.html

The library- or signature-based methods all require a certain amount of knowledge concerning the searched TEs. Library-based methods compare the genome sequence to a set of reference sequences corresponding to TE consensus (i.e. library) to search for their occurrences in the genome. It is thus an approach by sequence homology. The most known and used program from this category is *RepeatMasker* (Smit *et al.*, 1996–2010) whose search engines include *nhmmer*, *cross_match*, *ABBLAST/WUBLAST*, *RMBLAST* and *Decypher*. It relies on a library of consensus sequences of TEs called Repbase (Bao *et al.*, 2015). It is also able to identify low complexity DNA sequences, which can correspond to tandem repeats, by using sequence homology and the *Tandem Repeat Finder* program (Benson, 1999). The main outputs of the program are a global annotation of the repeats that are present in the query sequence as well as a modified version of the query sequence in which all the annotated repeats have been masked. Recently, a program has been developed to allow a more detailed analyses of one output as well as an easy way to retrieve the identified sequences (Bailly-Bechet *et al.*, 2014). Although *RepeatMasker* is fast and quite efficient, the main drawback consists in the need to already know the sequences of the TEs that are present in the genome under investigation or at least in not too far closely related ones. It is thus not possible by this approach to detect new TE families. The signature-based methods allow to have less knowledge concerning the searched TEs since they seek the genome sequence for nucleotidic or proteic motifs, or particular structural features from a specific class of TEs. LTR-retrotransposons can be identified based on their structure (presence of two direct repeats (LTR) at their extremities, size, presence of protein motifs inside the coding parts etc.) by different programs like *LTR_STRUC* (McCarthy and McDonald, 2003), *find_LTR* (Rho *et al.*, 2007), *LTR-finder* (Xu and Wang, 2007) and *LTRharvest* (Ellinghaus *et al.*, 2008). Outputs from *LTRharvest* can further be analyzed by *LTRdigest* (Steinbiss *et al.*, 2009) to annotate internal features of LTR-retrotransposons. These programs have various amount of success since they can find a lot of false positives, meaning that their output files need to be manually curated. They also are designed to find only full-length elements with two LTRs at both extremities of the element and sufficiently conserved. The identification of non-LTR retrotransposons has been the goal of some programs like *TSDfinder* (Szak *et al.*, 2002) and *SINEDR* (Tu *et al.*, 2004). DNA transposons can also be searched for using structural and sequence characteristics of such elements using programs like *TRANSPO* (Santiago *et al.*, 2002), *MUST* (Chen *et al.*, 2009), recently updated into a new version *MUSTv2* (Ge *et al.*, 2017), and *MITE-hunter* (Han and Wessler, 2010). All signature-based programs are thus mainly designed to help the researcher finding very specific types of TEs and thus concerning very specific biological questions since with these approaches, a large proportion of repeats remains ignored.

Alternatively to the precedent approaches, *ab initio* methods have been developed to detect virtually all kind of repeats in a genome without any *a priori* knowledge. These approaches can be separated into two distinct categories. In the first category, the methods first use self-comparison approaches of sequences to identify repeats and then use clustering methods to group them into families, before generating a consensus sequence for each detected family (method implemented in *RECON* (Bao and Eddy, 2003) or *PILER* (Edgar and Myers, 2005)). In the second category are grouped programs using k-mer and spaced seed approaches, which count “words” (method implemented in *ReAS* (Li *et al.*, 2005) or *RepeatScout* (Price *et al.*, 2005)). In that case, a repeat is defined as a subsequence that appears more than once in a longer sequence. All *ab-initio* programs have very varying rates of success in the identification of repeats depending on the data (quality of the genome assembly, proportion and age of the repeats in the genome). Moreover, the results produced by these methods are generally raw implying further analyses to identify the different type of repeats. To help with this step, some classification programs have been proposed like *TEclass* (Abrusán *et al.*, 2009), *REPCLASS* (Feschotte *et al.*, 2010), and *PASTEC* (Hoede *et al.*, 2014), which use structural features and sequence similarities to determine to which type of TE a sequence can be associated. The level of precision is variable according to the tool, *PASTEC* having currently the finer level in the assignation of TE type according to the classification proposed by Wicker and colleagues (Wicker *et al.*, 2007). Globally, no stand alone *ab initio* program can discover all repeated sequences present in a genome (Platt *et al.*, 2016). This is why approaches using several different programs to optimize repeat finding have been developed like, for example, the pipelines *REPET* (Flutre *et al.*, 2011) and *RepeatModeler* (Smit and Hubley; see Relevant Website section). They tend to give better results and have been largely used in the scientific community. For example, *RepeatModeler* has recently been used to identify TEs in the genome of a fungi (Castanera *et al.*, 2016) while this program was used in addition to *REPET* in the genome of the Atlantic salmon (Lien *et al.*, 2016).

A large number of tools also exist to detect specifically tandem repeats (see for a review Lim *et al.*, 2013). One of the most used tools to identify these sequences is the *Tandem Repeat Finder* program, which has been developed almost 20 years ago and that is still maintained by his developer (Benson, 1999). The algorithm of this program uses the approach of matching k-tuples, i.e. two windows of k consecutive characters from a nucleotide sequence that have identical content. This requires no *a priori* knowledge concerning the pattern of the repeat, its size or the number of copies. A similar approach is used in programs like *XSTREAM* (Newman and Cooper, 2007) and *MREPS* (Kolpakov *et al.*, 2003). Other programs use improved dynamic programming algorithms like *STAR* (Delgrange and Rivals, 2004) and *TRED* (Sokol *et al.*, 2007). More recently, the program *ReD tandem* (Audemard *et al.*, 2012) was developed using a flow based chaining algorithm. Some programs, like any type of dot-plot programs, are based solely on sequence self-alignment (SSA) algorithms, which are particularly efficient for the detection of long repeats. Their drawbacks are that these programs are relatively slow due to their time complexity and usually fail to identify short repeats.

Detection of Repeats in Unassembled Genomes

The development of the next generation sequencing (NGS) technologies has overturned our approach to genomics with a huge amount of data being produced everyday (Margulies *et al.*, 2005; Mardis, 2017). We thus now have access to more data on very various organisms at low cost and with fewer bias than the previous sequencing technologies (Wicker *et al.*, 2006). Currently however, the data produced by regular NGS technology like Illumina, correspond to rather short sequences due to the small size of the reads (maximum of 300 bp length) (Mardis, 2017). This short size implies that the assembly of the original DNA sequences is the most challenging and

time-consuming step especially when the considered organism is rich in repeats. To assemble a genome in this condition often leads to unfinished drafts of very numerous scaffolds, a large number of them corresponding to unplaced repeats on chromosomes.

By their repetitive nature, repeats represent portions of the genome with the best coverage, especially in the case of genome survey sequencing, where a sample of a complete genome is actually sequenced. Indeed, for a genomic coverage of 0.01X, each repeat having 1000 occurrences will theoretically have a coverage of 10X (Macas *et al.*, 2007). This situation has allowed the development of new approaches to detect repeats directly from the raw data, without the need for any homology search nor assembly.

The first method to have been developed based on this assumption and that is able to work with short reads is the AAARF algorithm (DeBarry *et al.*, 2008). This approach uses BLAST (Altschul *et al.*, 1997) to compare a read against all the others and obtain its nucleotide coverage. This value is used to determine overlapping reads that will be aligned to reconstruct a new sequence. Iteratively, the program will elongate each new sequence to assemble a set of TE contigs. Another type of approach that is also working on genomic sample is based on the construction of sequence clusters like the SeqGraphR program implemented in the RepeatExplorer pipeline (Novák *et al.*, 2010, 2013). In this method, reads are clustered using a hierarchical agglomeration algorithm. Various graph metrics are computed to discriminate between different types of repeats and the assembly of TE sequences gives consensus sequences. Based on a similar approach, the Transposome program has been proposed more recently that also uses a graph-based analysis of similarity between reads (Staton and Burke, 2015). As an alternative to read clustering, another approach, DNApipeTE (Goubert *et al.*, 2015), proposes to use the RNAseq assembler Trinity (Grabherr *et al.*, 2011) to build repeat contigs from genomic samples of less than 1X of coverage. The use of Trinity allows to recover alternative repeat consensus of a given family by producing distinct contigs for each structural variant. Alternatively, other tools like Tedna (Zytnicki *et al.*, 2014), RepARK (Koch *et al.*, 2014) and REPdenovo (Chu *et al.*, 2016) use directly a de Bruijn graph on the most represented k-mers to perform TE assembly.

Although the previous methods are supposed to be able to find any kind of repeats, they usually are best suited to discover TEs. They may be less powerful concerning tandem repeats. This is why some specific tools have been designed to specifically uncover tandem repeats from raw reads. The first tool, VNTRseek (Gelfand *et al.*, 2014), is a variant detection tool that compares reads in which tandem repeats have been detected using Tandem Repeat Finder (Benson, 1999) to a set of tandem repeats present in a reference genome. By this comparison, the variable number of tandem repeats is determined. A recent pipeline called TAREAN (Novák *et al.*, 2017) uses the principles of graph-based repeat clustering, as implemented in the RepeatExplorer pipeline, as well as tools facilitating the unsupervised identification and characterization of satellite repeats from raw reads. The reconstruction of the satellite sequences is based on k-mer decomposition and counting.

Globally, all these programs allow to determine the global proportion of repeats inside a genome, with sometime the possibility to estimate the copy number, as well as a catalog of the different types of repeats with the production of consensus sequences. However, since these programs work on raw reads, the information concerning the exact positions of these repeats is missing. Other approaches have thus been developed to specifically answer this question by comparing the copy number variation of repeats between two genomes.

Identification of the Repeat Copy Number Variation

When the first genomes were sequenced, it was considered that only one would be enough to understand the functioning and evolution of a given species. However, having only one genome is not enough to uncover the polymorphism existing among individuals. Particularly for repeats, some of which being able to move and replicate themselves in the genome, it is known that variations exist in term of copy number and insertion sites among natural populations (Petrov *et al.*, 2011; Boulesteix *et al.*, 2006). With the decrease in cost of sequencing, it is now possible to obtain data from several individuals of a given population and of several populations of a given species. This has opened the door to perform high throughput population genomics when using pooled sequencing data. Since it is not always possible to obtain good assembly with these data, new tools have been developed to specifically search for differences when compared to a reference genome. Thus, the goal of the bioinformatic tools developed for this purpose is to determine either one or the three types of TE insertions: insertions shared between the reference and the analyzed data (fixed insertions), and polymorphic insertions corresponding to insertions either absent from the analyzed data or absent from the reference genome (new insertions) (Fig. 2).

Several tools have been developed to determine the structural variation due to TEs in genomes and some attempts have been made to evaluate and review them (Ewing, 2015; Rishishwar *et al.*, 2016). The various methods have all in common in their process to first map the reads on a reference genome and/or on a set of annotated TE sequences before applying various filters and metrics to retain the informative ones. Then, two approaches exist that may be combined to analyze the results and to detect the presence/absence of a TE insertion. In the first approach, the program considers discordant read pairs, which are read pairs with one member matching uniquely on the reference genome sequence and the other matching on different copies from a TE family (Fig. 3(A)). This type of approach is used in the programs TE-locate (Platzer *et al.*, 2012), TraFiC (Tubio *et al.*, 2014) and TE-Tracker (Gilly *et al.*, 2014).

Fig. 2 The different types of TE insertions when comparing a reference genome and a newly sequenced one.

Fig. 3 Schematic representation of discordant read pairs (A) and split reads (B) that are used to identify TE insertion in raw data by comparison to a reference genome. Lines in black correspond to reads mapping on unique genomic regions and lines in red correspond to reads mapping on TE sequences.

The other approach consists in considering split reads, i.e., reads which overlap a junction between the genome and an inserted TE copies, with one part of the read mapping uniquely on the genome while the other part maps on TE sequences (**Fig. 3(B)**). The programs *RelocaTE* (Robb *et al.*, 2013), *ngs-TE-mapper* (Linheiro and Bergman, 2012), *TIDAL* (Rahman *et al.*, 2015), *ITIS* (Jiang *et al.*, 2015), and *T-Lex2* (Fiston-Lavier *et al.*, 2015) use this approach. Other programs use both approaches like *Tea* (Lee *et al.*, 2012), *RetroSeq* (Keane *et al.*, 2013), *TEMP* (Zhuang *et al.*, 2014), *Mobster* (Thung *et al.*, 2014), *Tangram* (Wu *et al.*, 2014), *TranspoSeq* (Helman *et al.*, 2014), *Jitterbug* (Hénaff *et al.*, 2015), *DD_Detection* (Kroon *et al.*, 2016), *popoolation_TE2* (Kofler *et al.*, 2016) and *MELT* (Gardner *et al.*, 2017). These different programs have been developed to answer specific biological questions, which make them either consider individual or population data to estimate the insertion frequency, to consider in majority polymorphic insertions (especially new insertions in the case of cancer research) but sometimes also shared insertions, and in some cases to take into account the genotype status of the detected insertions, i.e. if the insertion is present on only one (heterozygous) or two (homozygous) homologous chromosomes. For example, the program *T-Lex2* has been developed to compute the frequency insertions of TE copies that are present in the reference genome of *Drosophila melanogaster* in natural populations, whereas the program *Tea* has been developed to identify only new TE insertions in human cancers corresponding to somatic insertions.

Discussion

Repeats, and more particularly TEs, are important component of the eukaryote genomes that cannot be simply ignored when performing sequencing and assembly tasks. A lot of various bioinformatics tools have been developed during the last 20 years to allow a better handling of these particular sequences. Such tools need to evolve jointly with the evolution of sequencing technologies. Currently, one of the major problem with the current whole genome sequencing data produced to identify repeat insertions is the size of the available sequence reads (< 300 bp). Full-length TE insertions ranged between 500 bp to 10 kb, which implies that several reads are needed to cover an entire TE copy. This step may be particularly difficult since several insertions may present a very high degree of nucleotide identity between themselves. In that case, it is often impossible to recover some insertions and the only way to distinguish them is to take into account the genomic environment, i.e. the flanking regions around the insertion. However, sequence reads being shorter than the majority of TE insertions and reads overlapping the junction of the genomic region and the TE insertions being not numerous and difficult to map, this task is particularly challenging and lead to a loss of information. A way to tackle this difficulty is to produce longer reads. The third generation of DNA sequencing is currently under development and some already used techniques may be helpful, although still expensive or not optimized. For example, PacBio sequencing allows to produce sequences up to 20 kb but the rate of errors is still quite high (Mardis, 2017). However, this technique may be used in addition to short-read sequencing techniques to enhance the quality of a genome assembly (Pendleton *et al.*, 2015). The Illumina synthetic long-read technique has been successfully tested to perform the *de novo* assembly and resolve TE sequences in the genome of *Drosophila melanogaster* (McCoy *et al.*, 2014). However this technique is still expensive since the coverage that is needed is very high (Mardis, 2017). The MinION technology, which performs a single molecule sequencing, has been recently successfully used to detect new TE insertions in the plant genome *Arabidopsis thaliana* allowing to show that the high error rate of the technique could be compensated by the read length in this

particular question (Debladis *et al.*, 2017). Of course, as soon as these technologies will become the new standard, the current tools for TE analyses will become obsolete and new methodological procedures will need to be developed. In this way, a bioinformatic tool has recently been proposed to determine the presence/absence of TE insertions using reads produced by the PacBio technology (LorTE, Disdero and Filée, 2017).

Future Directions

The identification of TE insertions is also becoming very important in the field of epigenetics research. Indeed, TEs are known to be associated to particular epigenetic modifications that may impact the neighboring genes (Eichten *et al.*, 2012; Estécio *et al.*, 2012). Very few tools have been developed to allow the direct association between TEs and epigenetic modifications. For example, a web interface has been developed to specifically study histone modification enrichment of repeats taking advantage of their increased sequence coverage in ChIP-seq data (Day *et al.*, 2010). An advantage of this method is that it incorporates both ambiguously and uniquely mapped reads to avoid bias due to read mapping on consensus TE sequences. However, the results are not given at the insertion level and thus the information concerning the genomic environment of each insertion is lost. Several efforts have been made to develop methods allowing the association of small RNA data to TE sequences either at a global (*piPipes*, Han *et al.*, 2015) or at a individual copy level (*TEtools*, Lerat *et al.*, 2017). More recently, a new program has been developed allowing both the identification of new TE insertions and their associated DNA methylation in MethylC-seq data (*EpiTEome*, Daron and Slotkin, 2017). In summary, methodological efforts are still needed to study the epigenetic modifications directly associated to TE sequences. It is particularly important to consider the global sequence diversity of a TE family that may be very variable but also the genomic environment of a given insertion that may have consequences on the associated epigenetic modifications. These issues are currently difficult to handle due to the short size of sequence reads. However, as long read technologies will continue to be developed, it should open the door to new developments in a close future.

Closing Remarks

The domain of TE annotation in genome sequences is constantly producing new tools, which are supposed to outperform the previous ones and to offer new ways to handle the ever growing sequence data. However, the question of the impartial evaluation of these tools still remains. Indeed, the different tools have usually different competencies and may be at some point complementary. A clear problem underlying this situation is the lack of common standard data that would allow an unbiased estimation of any new tools (Hoen *et al.*, 2015). There is still room in that domain to propose various benchmarks according to the biological questions asked behind each tool.

Biographical Sketch

Emmanuelle Lerat is a CNRS researcher since 2005 working in the Laboratory “Biométrie et Biologie Evolutive” at the University Lyon 1, France. Her major research interest concerns the evolution of genomes in the light of their repeat content and more particularly the transposable elements (TEs). She has a strong background in molecular biology, in evolution, and in bioinformatics, with a long history in the annotation and analysis of TEs in various eukaryotic genomes, especially in *Drosophila*. She currently coordinates different subjects allowing to link informatic to biological questions concerning the functional impact of TEs on genome and gene evolution. She is a member of the Editorial Board of the international SBE journal “Genome Biology and Evolution” since 2008.

Bioinformatics Approaches for Studying Alternative Splicing

Introduction

Genes

Genes are genomic regions that contain necessary information for the expression of a protein or a molecule that ultimately helps in the survival, reproduction and function of the organism. The information stored in the DNA sequence of a gene is first transcribed into an RNA molecule, by RNA polymerase. For the protein coding genes, this transcript is called a messenger RNA (mRNA) which is then translated to synthesize proteins. The nascent RNA (pre-mRNA) transcripts contain intervening sequences, known as the *introns*, that do not become part of the final mRNA (Gilbert, 1978). The regions of pre-mRNA that are retained and ligated for translation are known as *exons*. The *introns* are removed from nascent RNA by a mechanism known as *splicing*. The spliced mRNA molecule forms a continuous protein-coding region ready to be translated into a protein molecule. Nearly all eukaryotes share the presence of *introns* and the mechanism of RNA *splicing*. The presence of introns plays a major role in facilitating recombination of RNA sequences and helps in developing protein diversity (Rogozin *et al.*, 2012). For a better understanding of the bioinformatics tools and approaches used to study alternative splicing, it is necessary to have a brief overview of the elements and mechanisms involved in splicing.

Eukaryotic vs Prokaryotic Splicing

Eukaryotes have devised a complex mechanism of modifying their primary RNA transcripts. Using this mechanism, called “*splicing*”, the nascent mRNA is processed so that the *introns* are selectively excised out and *exons* are ligated together. Splicing is catalyzed by a mega-dalton multi-ribonucleoprotein (RNP) complex known as the “*spliceosome*” (Will and Lührmann, 2011). The spliceosome is composed of five small nuclear RNPs (snRNPs) and numerous proteins. *Splicing* is more prevalent in higher eukaryotes and leads to the expression of a higher number of unique proteins from a single gene (Nilsen and Graveley, 2010). On the other hand, protein coding genes in prokaryotes lack introns which is complemented by the lack of a spliceosomal machinery (Rogozin *et al.*, 2012). This is why bacterial genes have a one-to-one correspondence of bases between a gene and its mRNA. However, some bacteria and viruses do contain some rare introns in non-coding RNAs that have been observed to self-splice *in vitro* (Woodson, 1998; Belfort, 1990; Schmidt, 1985; Berget *et al.*, 1977; Chow *et al.*, 1977). Presence of introns in early life forms has been discovered recently and this still remains a confounding fact (Roy and Gilbert, 2006).

Spliceosome and the Mechanism of Splicing

The post-transcriptional modification of the nascent mRNA (pre-mRNA) for the removal of introns is catalyzed by the spliceosome. The spliceosome is a large RNP complex composed of five snRNPs (U1, U2, U4, U5 and U6) and other accessory proteins (Staley and Guthrie, 1998; Jurica and Moore, 2003). Fig. 1 depicts various elements of the spliceosome. Each snRNP contains the corresponding uridine rich non-coding small RNA molecule (snRNA) and a variable number of complex-specific proteins (Hoskins *et al.*, 2011). Another variant of the spliceosome is known to exist; it is composed of other functionally analogous snRNPs and splices a rare class of introns (Patel and Steitz, 2003). Below, we describe the mechanism that relates to the well-explored and major spliceosome.

Fig. 1 Alternative splicing mechanism and events. Splicing factors recognize different sequences along the pre-mRNA. Conserved recognition sequences include intron boundaries named 5 ss and 3 ss. These elements interact with the spliceosome, recruiting snRNPs (U1, U2, U4, U5 and U6). Other regulatory elements are embedded in the exon (ESE, ESS) or in the intron (ISE) and could be recognized by proteins of the SR and/or hnRNP families.

The splicing reaction is a coordinated series of RNA–RNA, RNA–protein and protein–protein interactions (Trowitzsch *et al.*, 2009; Hoskins and Moore, 2012). First, U1 binds to the 5' splice site of an exon and U2 binds near branch point sequence (BPS) just upstream of the 3' splice site of the adjacent exon (Peled-Zehavi *et al.*, 2001). The U1 and U2 binding is important for the intron definition, thus for the accuracy of the splicing reaction. Later, a tri-snRNP complex, composed of U4/U6 and U5, joins in and leads to the formation of an active complex that catalyzes splicing. Once the splicing is over, the spliceosome disassembles and all components are recycled for future splicing reactions (Hnilicova and Stanek, 2011). Each splicing alternative is regulated through an interplay between constitutive splicing motifs, such as 5' splice sites, branch points, poly-pyrimidine tracts and 3' splice sites and components of the core splicing machinery. Exons and introns often contain *cis*-regulatory sequences, intronic enhancers or silencers that affect the splicing in a positive and negative manner. Splicing regulatory sequences (enhancer or silencer) are usually 6–10 base pair (bp) in length and induce binding of specific regulatory proteins such as serine/arginine rich (SR) proteins or heterogeneous nuclear ribonucleoproteins (hnRNPs) (Black, 2003; Wang and Burge, 2008; Chasin, 2007; Han *et al.*, 2010).

Types of Splicing

Splicing of a multi-exon pre-mRNA transcripts leads to two or more distinct mRNA products (Black, 2003; Wang and Burge, 2008; Nilsen and Graveley, 2010; Calarco *et al.*, 2011). Based on the complexity of the events, two different types of splicing have been described: *constitutive* splicing and *alternative* splicing (van den Hoogenhof *et al.*, 2016). *Constitutive splicing* (CS) is the process where the introns are removed from the pre-mRNA and the exons are joined together to form a mature mRNA. On the other hand, *alternative splicing* (AS), is the process where exons can be included or excluded in different combinations to create a diverse range of mRNA transcripts from a single pre-mRNA (Nilsen and Graveley, 2010). Computational and experimental studies have concurred that splicing signals at AS sites are weaker, the length of AS exons are shorter than that of CS exons, skipped exons tend to preserve the reading frame at a greater frequency than CS, and orthologous AS are more conserved than orthologous CS (Zheng *et al.*, 2005; Clark and Thanaraj, 2002; Garg and Green, 2007). Because of a rising interest towards AS in past years, this article is focused on it.

Alternative Splicing and its Mechanism

Alternative splicing (AS) is a mechanism by which one gene gives rise to multiple protein products with different functions (Roy *et al.*, 2013; Brett *et al.*, 2002). It was discovered when two different mRNA species were observed to be encoded by the same gene (Early *et al.*, 1980; Rosenfeld *et al.*, 1982). Recent high-throughput transcriptome analysis has suggested that about 95% of the mammalian multi-exonic genes are subjected to AS (Pan *et al.*, 2008). Four main AS events have been reported in literature namely, exon skipping, intron retention, alternative donor and alternative acceptor splice sites. AS events can be classified into different splicing patterns that include cassette exons, mutually exclusive exons, retained intron, alternative 5' splice sites, alternative 3' splice sites, alternative promoters, and alternative poly-A sites (Fig. 2; Keren *et al.*, 2010; Chen, 2011). Among them, the most common type of alternative splicing is including or skipping a cassette exon in the mature mRNA. In cassette exons, internal

Fig. 2 Types of alternative splicing.

exons can either be included or excluded from the mature mRNA (Zhang *et al.*, 2016). In case of intron retention, the excision of an intron can be suppressed, which results in the retention of the entire intron and exons can be extended or shortened through the use of alternative 5' or 3' splice sites. In contrast, alternative promoters and alternative poly-A sites are alternative selection of transcription start sites or poly-A sites and are not due to alternative splicing. Incompletely spliced transcripts may contain intron fragments that can be inaccurately identified as intron retention, so it is hard to distinguish them from experimental artifacts. In general, intron retention is the most difficult AS event to detect. Many genes have multiple alternative splicing events with complex combinations of exons and produce diverse transcript isoforms. Most interesting example is, *Drosophila melanogaster's* Down syndrome cell adhesion molecule (Dscam) gene contains 20 constitutive and 95 cassette exons. These 95 cassette exons can express 38,016 different mature mRNAs (Graveley *et al.*, 2004; Missler and Sudhof, 1998).

Alternative Splicing Regulation

As already mentioned, AS increases the proteomic diversity in cells to adapt to various conditions. Therefore, it is important that AS be precisely regulated. Except the minimal core elements 5' splice site, 3' splice site and BP that are crucial for defining splicing sites, there are others instructions that help in discriminating between correct and incorrect splice sites and play important roles in AS regulation. These instructions are called as (exonic or intronic) splicing enhancers and/or silencers which are represented as 4–10 nucleotides. Two major classes of widely expressed *trans*-acting factors that are involved in binding these sequences and thus in controlling of splice site recognition are the SR proteins and heterogeneous ribonucleoproteins (hnRNPs). SR proteins got their name according to the domain enriched in dipeptides arginine/serine (RS). They bind to the pre-mRNA by their N terminal domains which is an RNA recognition motif (RRM) and mediates protein-protein interaction by SR domain facilitating assembly of spliceosome proteins (Long and Javier, 2009). Bradley and colleagues found that all eight SR proteins in *Drosophila* affect approximately 560 endogenous simple ASS events proving that they are indeed the key regulators of AS (Bradley *et al.*, 2015). The splicing repressor family of proteins are hnRNPs that were first identified as proteins that interact with heterogeneous nuclear RNA. They have their roles in telomerase maintenance, mRNA stability, regulation of transcription and translation (Geuens *et al.*, 2016). Several of the hnRNPs are identified as splicing repressors that suppress splicing by different mechanisms such as directly displacing snRNP binding, blocking interaction between U1 and U2 snRNP or looping out exons (Martinez-Contreras *et al.*, 2007). It is worth to mention that nuclear concentration of regulators help proper splicing patterns and that SR as well as hnRNP proteins control their own splicing patterns. At the end, these proteins can compete for binding to an overlapping ESE/ESS element (Zahler *et al.*, 2004) and this binding competition between them provides a combinatorial control in final decision of splice site choice.

Tissue-Specific AS in Humans

AS is considered an important mechanism for tissue-specific expression of transcript isoforms in humans. Recent EST based analyses have shown that the human brain contains highest fraction of alternatively spliced genes, followed by the liver and testis whereas human muscle, uterus, breast, stomach and pancreas were observed to have the lowest levels of genes undergoing AS (Lee *et al.*, 2003; Xu *et al.*, 2002; Stamm *et al.*, 2000). Moreover, human AS events have different usage pattern of alternative 5' splice site exons (A5Es) or alternative 3' splice site exons (A3Es). These studies suggest that the fraction of genes containing A3Es and A5Es have significantly high in the liver as in any other human tissue (Yeo *et al.*, 2004). Brain was observed to be the tissue with the second highest level of alternative usage for both 5' splice sites and 3' splice sites whereas muscle, uterus, breast, pancreas and stomach have shown the lowest level of A5Es and A3Es (Yeo *et al.*, 2004). AS events variation in human tissues are primarily regulated by *trans*-acting factors that bind on exonic and intronic *cis*-acting RNA elements (CAEs). A computational study using publicly available Affymetrix Genechip Human Exon Array dataset identified 652 *cis*-acting RNA elements (CAEs) across 11 human tissues (Wang *et al.*, 2009). Approximately, one third of all predicted CAEs matched with exonic splicing regulator databases and the vast majority of predicted CAEs were observed in the intronic regulatory regions. Most of these CAEs contribute to the AS between two tissues, while some are important in multiple tissues. Overall, the analysis suggests that genome-wide AS patterns are regulated by a combination of tissue-specific *cis*-acting elements and "general elements" whose functional activities are important but differ across multiple tissues (Wang *et al.*, 2009).

Bioinformatics Approaches for AS Detection

Until recently, systematic analysis of AS was done using expressed sequence tags (EST) (Gupta *et al.*, 2004; Sorek *et al.*, 2004; Xie *et al.*, 2002) or splicing-specific microarrays (Castle *et al.*, 2008; Clark *et al.*, 2002; Pan *et al.*, 2008). However, the detection of alternative splicing events has been significantly improved by next-generation sequencing (NGS). From this data, AS is identified through bioinformatics approaches by aligning the EST sequences with mRNA and genomic sequences using sequence alignment tools (Kim and Lee, 2008). Genomic sequence acts as the main reference sequence for detection and validation of AS events. With the availability of high-throughput techniques, multiple genomes have been sequenced and it has become feasible to study AS on a genomic scale (Pan *et al.*, 2008; Wang *et al.*, 2008). Therefore, a large number of alternative transcripts have been discovered along with extraction of distinctive features of alternatively spliced exons using bioinformatics (Roy *et al.*, 2013). With the

advances in tools used to study AS, it has also become easier to uncover the splicing dysregulations that lead to diseases. It is observed that dysregulation of alternative splicing affects various human conditions, including cancers (Ghigna *et al.*, 2010; Yap and Makeyev, 2013; Mills and Janitz, 2012; Poulos *et al.*, 2011; Mittendorf *et al.*, 2012; Manetti *et al.*, 2011; Endo-Umeda *et al.*, 2012; Medina and Krauss, 2013; Bogdanov, 2006; Lara-Pezzi *et al.*, 2012; Cooper, 2005; Miura *et al.*, 2011; Sampath and Pelus, 2007; Hagen and Ladomery, 2012; Yi and Tang, 2011; Omenn *et al.*, 2010). Databases like dbSNP (see “Relevant Websites section”) and ssSNPTarget (see “Relevant Websites section”) help to search for the splice site SNPs located in the genes of interest for the identification of any association to diseases (Tang *et al.*, 2013). These tools prove helpful in developing new splicing-targeted drugs or therapeutics.

AS detection usually involves three distinct stages. During the first step, transcript and genomic sequence data are processed to eliminate repetitive or ambiguous sequences. Poly-A tails are also removed during this pre-processing even though there may be some genuine poly-A genomics sequences. Second, the transcript sequences are aligned to the genomic sequence and “gene models” are deduced. The alignment to genomic sequence can be performed using tools like BLAT, GMAP or SPA (Kent, 2002; Wu and Watanabe, 2005; van Nimwegen *et al.*, 2006) with or independent of SIM4 (Florea *et al.*, 1998). Next, several possible alignments for a given sequence are screened out by choosing only the best hit as measured by percent identity and alignment coverage. Rest of the unspliced alignments can be removed if strictly focused on AS detection. Third, each of the alternative splicing events are identified and various alternative “gene models” are constructed. In order to exclude artifacts, individual AS events only consist of a pair of genomically non-overlapping splicing events. From here, liberal methods generate all possible combinations of the splicing events (splicing graphs) whereas more conservative methods seek only a minimal set of isoforms. Below, we present an overview of the role of bioinformatics approaches and tools in detecting alternative splicing along with its relevance in present era and challenges involved.

AS detection using sequence alignment: We can identify alternative splicing events by aligning ESTs with genomic and mRNA sequences using alignment tools like BLAST, BLAT (BLAST-Like Alignment Tool) or ClustalW. Using the alignment between ESTs and genomic sequences, one can detect the locations of exons and introns, and then by comparing their structures we can identify the alternative splicing events. For identifying alternative splicing by sequence alignment, we can further use alignment tools like GMAP or SPA to correct the genome alignments and generate valid alignments. Once we have identified the alternative splicing events, we can construct full-length alternatively spliced transcripts using graphical display tools including “Splice graph”. Although these alignments based methods are rapid, possible limitations that could affect the analysis include high sequencing errors, contamination, misalignments, low sequence coverage of ESTs.

AS detection using sequence conservation: AS events are conserved among different organisms *e.g.*, human and mouse, and therefore are of biological importance. Comparative genomics can provide us different means to predict the conserved exons that were spliced alternatively featuring the evolutionarily conserved alternative splicing events. As alternative exons have comparatively higher conservation level than constitutive exons in flanking intronic regions, hence can be used as good identifier for the alternative splicing (Chen, 2011).

AS detection using microarray data analysis: The above mentioned two approaches of sequence alignment and comparative genomics for identification of alternative splicing events, provides us only with the existence of an alternative splicing event but neither the degree nor the regulation of these alternative splicing events. The microarray study can provide us quantity of an alternative splicing event for a particular stage, condition or tissue of a cell. Previously, Affymetrix exon arrays were used by researchers to identify tissue-specific exons (Clark *et al.*, 2007) and differentially expressed AS between different human-cells (Yeo *et al.*, 2007). Some of the tools or methods that have been used widely for the alternative splicing microarray data analysis includes the splicing index calculation, Analysis of splice variation (ANOSVA), Finding isoforms using robust multichip analysis (FIRMA), a gene structure-based splice variant deconvolution method (DECONV), splicing prediction and concentration estimation (SPACE), and Generative model for the alternative splicing array platform (GenASAP). The details along with pros and cons of these methods is well described (Chen, 2011).

AS detection using RNA-seq data analysis: Alternative splicing is considered as main mechanism governing protein diversity and gene regulation. With the advancement of RNA-seq technology. It is possible to analyze the global impact and regulation of this biological process. There are increasing number of studies illustrates that the selection of wrong splice sites causes human disease. Therefore, the identification and quantification of differentially spliced transcripts are crucial for RNA-seq analysis.

Splicing Efficiency

Splicing efficiency (SE) (or splicing score; or splicing index) is used for the quantification of alternative splicing. SE is calculated as the ratio between the amounts of (spliced) mRNA and the (nascent) pre-mRNA. The conventional approach of using real-time quantitative PCR (RT-qPCR) with primers spanning exon-intron and exon-exon junctions (Hao and Baltimore, 2013) to determine SE is feasible for only a limited number of genes. However, with the availability of strong computational hardware and bioinformatics tools that can analyze the large amounts of RNA-seq data, it is now possible to determine genome-wide SE. Using RNA-seq data, several approaches have been used for calculating SE based on RNA-seq read counts from intronic, exonic or exon-exon junctions (Herzel and Neugebauer, 2015; Volanakis *et al.*, 2013). Below, we provide the main approaches for calculating SE (or scores):

- 1) *Exon-centered splicing score (ECSS):* ECSS is calculated using the splicing frequency around a given exon, by subtracting the read coverage over 2 kb of the upstream intron from the read coverage over 2 kb of the 5' end of the downstream intron (Pandya-Jones, 2011; Tilgner *et al.*, 2012).

- 2) *Intron-centered splicing score (ICSS)*: ICSS for each intron is calculated as the ratio of reads around the 3' splice site. The read coverage over the last 25 bp of a given intron is divided by the read coverage over the first 25 bp of the downstream exon (Carrillo Oesterreich *et al.*, 2010).
- 3) *Gene-based splicing score (GBSS)*: It is the splicing frequency for each gene, by dividing the read coverage over exons by the read coverage over the whole locus (Bhatt *et al.*, 2012).

ECSS is optimal for alternative cassette exon usage. However, it is not suitable for the first and terminal exons which have to be analyzed differently. Using ICSS, first and terminal exons can be included in the analysis but short exons are a disadvantage. In GBSS, the noise is reduced by the involvement of many reads in the analysis. However, this approach neither provides SE for individual introns nor any information about AS events per gene. The user may refer to Brugiolo *et al.* for further discussion regarding calculation of splicing efficiency using bioinformatics analysis (Brugiolo *et al.*, 2013).

Application of RNA-seq for Analyzing AS

RNA-sequencing (RNA-seq) uses next generation sequencing technology to sequence DNA molecules reversely transcribed from mRNAs. It has allowed the identification of RNA populations like miRNAs, lncRNAs, and several other species of RNA that in fact have opened new areas of biology (Lynch, 2015). Using RNA-seq data, it is indeed easier to quantify gene expression, previously unknown coding or non-coding transcripts, the composition of various isoforms, and study events like RNA editing, gene fusion and nucleotide variations. RNA-seq also provides an unprecedented opportunity to study AS quantitatively in a systematic way (Feng *et al.*, 2013). In recent years, many researchers used RNA-seq analysis to study AS. The bioinformatics tools and steps involved in the quantitative study of AS with RNA-seq are now well established, including visualization approaches (Feng *et al.*, 2013; Liu *et al.*, 2012; Song *et al.*, 2016; Mezlini *et al.*, 2013; Li *et al.*, 2011; Rogers *et al.*, 2012; Barann *et al.*, 2017). Therefore, several groups have studied AS using RNA-seq data. Pan *et al.* (2008) used RNA-seq for the first time to analyze the complexity of AS in 5 different human tissues. They estimated that about 95% of multi-exon genes undergo AS and discovered thousands of new splice junctions, as demonstrated by earlier studies as well (Sultan *et al.*, 2008). This observation was later corroborated by Wang *et al.* (2008) who analyzed the RNA-seq data from 15 different human tissue samples and cell line transcriptomes and observed that 92%–94% of human genes undergo AS. The same study also analyzed tissue-specific AS regulation, individual specific AS isoform variation, and alternative cleavage and polyadenylation (APA) events using RNA-seq data. Several important diseases that precipitate due to erroneous splicing have been studied using RNA-seq data (Garcia-Blanco *et al.*, 2004). Many studies have studied AS in the context of highly complicated diseases like cancer (Kalari *et al.*, 2012; Ren *et al.*, 2012; Shapiro *et al.*, 2011). In order to study genome-wide splicing regulation and mechanisms involved in transcriptome-splicing coupling, it is also possible to integrate many human RNA-seq datasets to identify splicing modules – a unit in the splicing regulatory network (Dai *et al.*, 2012; Li *et al.*, 2012). Schreiber *et al.* (2015) used the RNA-seq data from *Saccharomyces cerevisiae* to assess the impact of AS on its transcriptome. The detection of AS events has rapidly advanced with NGS in spite of the limitation due to the short sequencing read length. The upcoming 3rd generation sequencing technology like PacBio and Nanopore meant for long reads of RNA-seq will hopefully resolve these limitations in future.

Bioinformatics Tools for AS Detection

Several software tools have been developed for the identification of alternatively spliced exons and isoforms during the last decade. Herein, we are highlighting basic characteristics of some of the commonly used tools:

AStalavista (2007): AStalavista (Alternative Splicing transcriptional landscape visualization tool) is the first tool (a web server) for the dynamically and exhaustive extraction of complex AS events from annotated genes in order to compare different types of AS and distributions (Foissac and Sammeth, 2007). It is a JAVA-based tool available as a web server provided in “Relevant Websites section” and the latest version can be downloaded from the website provided in “Relevant Websites section”. For any given set of transcripts annotated with known exon–intron structure, AStalavista first performs an exhaustive pairwise comparison between all transcripts in a locus. To ensure an exhaustive detection of AS events, it pools all transcripts from a single transcriptional locus that overlap on the same strand of the genome sequence. It then dynamically assigns an AS code to the splicing events observed based on the relative position of splice sites. This code helps in automatic identification and exhaustive extraction of variations in the exon–intron structure (Sammeth *et al.*, 2008). AS events of the same type are given an identical code and classified in the same structural group whereas a new, concise and univocal AS code is assigned to each of the variant splicing structures. This generic protocol is applicable to any genome with or without annotation. Hence, AStalavista has an advantage over other methods that otherwise require a predefined splice form (as a reference transcript) for comparison. It detected more than 24,000 AS mechanistically un-elucidated events involving more than two alternatives in humans (Sammeth, 2009). Using this analysis, AStalavista generates a ranked list for each detected event type with its unique code (relative-position notation) and builds an AS landscape (in the form of a pie chart) for the given set of transcripts. This landscape of AS events can be used to investigate the transcriptome diversity across genes, chromosomes, and species.

AltAnalyze (2010): AltAnalyze (see “Relevant Websites section”) is a comprehensive tool for performing the analysis of alternative splicing data from Affymetrix Exon and Gene Arrays and their functional prediction at proteins and domains level (Emig *et al.*, 2010). It requires neither any programming knowledge nor any exon-array analysis expertise. It was designed for

computing alternative exon statistics based on the widely used rigorous statistical methods like FIRMA and MiDAS using ‘detection above background’ (DABG) *P*-value thresholds with other alternative exon analysis parameters for any number of raw Affymetrix CEL files. AltAnalyze provides outputs in tab-delimited text file format which can be either opened with Microsoft Excel like spreadsheet programs or can be visualized with DomainGraph (see “Relevant Websites section”) for further analysis.

GPSeq (2010): GPSeq is a tool to analyze RNA-seq data to estimate gene and exon expression, identify differentially expressed genes (DEGs), and differentially spliced exons (DSEs) through log-likelihood ratio approaches (Srivastava and Chen, 2010). It is based on a two-parameter (i.e., θ and λ) generalized Poisson (GP) model to fit to the position-level read counts across all of the positions of a gene/exon. Here the estimated parameter θ represents the transcript amount for the gene and λ represents the average bias during the sample preparation and sequencing process. After normalization of mapped reads a likelihood ratio test is used to identify DEGs or DSEs by treating the λ estimates as true values. Moreover, a simulation strategy can be adopted to better estimate the *P*-values. It deals with the fundamental problem of the distribution of the position-level read counts by proposing a two-parameter generalized Poisson (GP) model. This GP model fits the data much better than the traditional Poisson model by separating true signals from sequencing bias and aids in the better estimation of gene or exon expression, in performing a more reasonable normalization across different samples, and hence improve the identification of DEGs as well as DSEs. More importantly, it can deal with multiple RNA-seq data sets. The codes for the GP model were written in C and ‘GPseq’ is an R-package to implement all these methods available for download at the website provided in “see Relevant Websites section”. This tool is not available anymore.

MISO (2010): Mixture of Isoforms (MISO) is a statistical model that quantitates the expression level of alternatively spliced genes from RNA-seq data, and identifies differentially regulated isoforms or exons across samples (Katz et al., 2010). MISO model uses Bayesian inference by modeling the generative process to reproduce the reads from isoforms in RNA-seq for calculating the probability that a read originated from a particular isoform. It treats the expression level of a set of isoforms as a random variable and estimates a distribution over the values of this variable using a sampling based algorithm known as Markov Chain Monte Carlo (“MCMC”). These estimates can be quantified by the confidence intervals. It not just estimates the expression level of a single alternatively spliced exon (“exon-centric”), or of each transcript belonging to a gene (“isoform-centric”), but can quantify the levels of multiple isoforms produced by several nearby alternative splicing events. ISO is available as a Python package at the website provided in “Relevant Websites section”. It outputs the results as the exon/isoform expression levels in each sample along with confidence intervals which can be visualize alongside the RNA-seq data with sashimi-plot.

JuncBASE (2011): JuncBASE is used to identify and classify alternative splicing events from RNA-seq data (Brooks et al., 2010). JuncBASE is available from the GitHub repository located at the website provided in “Relevant Websites section”. Alternative splicing events are identified from splice junction reads from RNA-seq read alignments and annotated exon coordinates. JuncBASE also uses read counts to quantify the relative expression of each isoform and identifies splice events that are significantly differentially expressed across two or more samples.

SpliceTrap (2011): SpliceTrap is a method to quantify local exon inclusion levels by estimating the expression-levels of each exon using paired-end RNA-seq data (Wu et al., 2011). SpliceTrap generates alternative splicing profiles for different splicing patterns, such as exon skipping, alternative 5’ or 3’ splice sites, and intron retention. It can also identify major classes of alternative splicing events under a single cellular condition, without requiring a background set of reads to estimate relative splicing changes. It utilizes a comprehensive human exon database called TXdb (see section “Bioinformatics Approaches for AS Detection”) to estimate the expression level of every exon as an independent Bayesian inference problem. Unlike microarray-based methods, SpliceTrap relies on RNA-seq, and therefore it can determine the inclusion level of every exon within a single cellular condition, without requiring a background set of reads. Compared to Cufflinks and Scripture, it was shown to improve the accuracy, robustness and reliability in quantifying a large fraction of AS activity. SpliceTrap is useful in studying changes at the single-exon levels and can be helpful in the discovery of nearby *cis*-regulatory elements in diverse applications. It can also be implemented online through the CSH Galaxy server the website provided in “Relevant Websites section” and is also available for download and installation at the website provided in “Relevant Websites section”.

MATS (2012): MATS is a computational tool to detect differential AS events from RNA-seq data (Shen et al., 2012). The statistical model of MATS calculates the *P*-value and false discovery rate that the difference in the isoform ratio of a gene between two conditions exceeds a given user-defined threshold. From the RNA-seq data, MATS can automatically detect and analyze AS events corresponding to all major types of AS patterns. MATS handles replicate RNA-seq data from both paired and unpaired study design and has been designed to handle two RNA-seq samples.

SpliceSeq (2012): SpliceSeq is a Java based application, freely available at the website provided in “Relevant Websites Section”, for visualization and quantitation of RNA-seq reads for alternative splicing and to identify potential functional changes resulted from splice variation (Ryan et al., 2012). It aligns RNA-seq reads to gene splice graphs for accurate analysis of large and complex transcript variants. Firstly, an alignment database is generated from the imported RNA-seq data by using Bowtie and then SpliceSeq aligns reads to the splice graphs or gene models. Further, it evaluates the patterns of predicted transcript splicing for AS events and classifies these events in different types including exon skip, cassette exons, alternate promoter etc. The resulted alternative protein sequences are predicted with the weighted traversal of each gene’s splice graph.

SplicingViewer (2012): SplicingViewer is an integrated tool, freely accessed at the website provided in “Relevant Websites section” for detecting the splice junctions from known gene models or RNA-seq data, annotating the alternative splicing patterns using the splice junctions and visualizing these patterns (Liu et al., 2012). Firstly, the RNA-seq short reads are mapped to the provided or selected reference genome using aligners like BWA, Bowtie and SOAP. The mapped data are then converted to SAM/

BAM format by SAMtools to be used in SplicingViewer as input for further analysis and display alternative splicing patterns and the RNA-seq mapping result with a user-friendly interface, in a memory efficient and quick manner.

ASprofile (2013): ASprofile is computational framework for the identification of AS events in different RNA-seq samples (Florea et al., 2013). It comprises of three main programs for extracting (*extract-as*), quantifying (*extract-as-fpkm*) and comparing (*collect-fpkm*) AS events from transcripts assembled from RNA-seq data in multiple conditions. First, *extract-as* program takes as input a GTF transcript file and compares all pairs of transcripts within a gene to determine exon-intron structure differences that indicate an AS event. Second, *extract-as-fpkm* calculates the FPKM of each AS event from those of transcripts. Finally, *collect-fpkm* collects the FPKM event values for all RNA-seq samples, calculates and compares splicing ratios across samples.

ASprofile are providing following types of AS event such as exon skipping (SKIP), cassette exons (MSKIP), alternative transcript start and termination (TSS, TTS), retention of single or multiple introns (IR, MIR), and alternative exon (AE). ASprofile has been implemented using RNA-seq data from Illumina's Human Body Map project and authors have provided global view of alternative splicing events in 16 different human tissues. The list of all AS events catalog and the ASprofile software are freely available and can be access through their web site the website provided in "Relevant Websites section".

DiffSplice (2013): DiffSplice is tools for the identification and quantification of alternative splicing events (Hu et al., 2013). This software is available at the website provided in "Relevant Websites section". This approach starts with the identification of alternative splicing module (ASMs) from the splice graph that created directly from the exons and introns predicted from RNA-seq read alignments. The abundance of alternative splicing isoforms residing in each ASM is estimated for each sample and is compared across sample groups. DiffSplice takes as input the SAM files and results are summarized as a decomposition of the genome. It can be visualized using the UCSC genome browser. The approach does not depend on transcript or gene annotations. It evades the need for full transcript inference and quantification, which is a usually difficult because of short read lengths, as well as various sampling biases.

DSGseq (2013): DSGseq is method to identify differentially spliced genes between two groups of samples by comparing read counts on all exons (Wang et al., 2013). DSGseq software is available at the website provided in "Relevant Websites section". DSGseq tools is use negative binomial (NB) distribution to model sequencing reads on exons, and propose a NB-statistic to detect differentially spliced genes between two groups of RNA-seq samples by comparing read counts on all exons. It produces the tabular output the differences in the relative abundance of the isoforms of each gene in two groups of samples and relative abundance of the isoforms of each exon in each gene. It also ranks the exon that the most significant difference. This is a novel exon-based approach and it does not need isoform composition information and isoform expression estimation. Experiment on simulated and real RNA-seq data shows that this method has good performance and applicability. DSGseq method can identify the exons that contribute the best to the differential splicing. It can also identify previously unknown alternative splicing events.

GLiMMPs (2013): GLiMMPs (Generalized Linear Mixed Model Prediction of sQTL) is a robust statistical method for detecting splicing quantitative trait loci (sQTLs) from RNA-seq data (Zhao et al., 2013). It works at a low false positive rate and characterizes the genetic variation of alternative splicing. It takes into account the individual variation in sequencing coverage and the noise prevalent in RNA-seq data. To begin with, it needs a set of identified AS events and RNA-seq reads mapped to splice junctions detected for the estimation of the exon inclusion levels. GLiMMPs uses the reads information from both exon inclusion and skipping isoforms to model the estimation uncertainty of exon inclusion level. The source code used to be available from the website provided in "Relevant Websites section". However, currently, it appears to be discontinued.

SpliceR (2014): SpliceR is an R package for classification of alternative splicing and prediction of coding potential (Vitting-Seerup et al., 2014). SpliceR is implemented as an R package based on standard Bioconductor classes and is freely available from the Bioconductor repository (see "Relevant Websites section"). spliceR uses the full-length transcript output from RNA-seq assemblers (like *Cufflinks*) to detect single or multiple exon skipping, alternative donor and acceptor sites, intron retention, alternative first or last exon usage, and mutually exclusive exon events. For each gene, spliceR constructs the hypothetical pre-RNA based on the exon information from all transcripts originating from that gene. Subsequently, all transcripts are compared to this hypothetical pre-RNA in a pairwise manner. AS events are classified and annotated. It is flexible and can be easily integrated in existing pipelines or workflows. It predicts coding potential of transcripts, calculates untranslated region (UTR) and open reading frame (ORF) lengths. Moreover, it also predicts whether transcripts are nonsense mediated decay (NMD)-sensitive based on compatible annotated start codon positions and their downstream ORF.

GESS (2014): Graph-based exon-skipping scanner (GESS) is computational method to detect *de novo* exon-skipping events directly from raw RNA-seq data without the prior knowledge of gene annotation information (Wang et al., 2017). It can also detect the dominant isoform among the skipping- or inclusion- isoforms, generated for these skipping event sites and presents a more accurate and comprehensive data of skipping events associated with a particular physiological condition within a cell. GESS tools is available at the website provided in "Relevant Websites section". First, a splice-site-link graph is created from the splicing-aware aligned reads using a greedy algorithm. The sub-graphs are navigated iteratively by implementing a walking strategy to reveal a pattern corresponding to an exon-skipping event. Finally, the MISO model is implemented to obtain the ratio of skipping isoform *vs.* inclusion isoform and the dominated isoform is determined. In this method, the input must be sorted bam file and exon-skipping sites output from GESS can be use by MISO for Ψ -value (Percent Spliced Isoform) calculation. GESS method is capable of capturing *de novo* exon-skipping events directly from using raw RNA-seq reads.

rMATS (2014): As described previously, MATS works for detecting differential AS between two RNA-seq samples. Similarly, rMATS can be used to detect differential AS from replicate RNA-seq data using a hierarchical model to highlight the sampling

uncertainty in individual replicates and the possible variability among them (Shen *et al.*, 2014). rMATS is flexible in testing the splicing difference above any user-defined threshold. Being a general method for analyzing mRNA isoform ratios from read-counts, rMATS method can also be used for sequencing-based analyses of other types of mRNA isoform variations including alternative polyadenylation and RNA editing. The rMATS source code is freely available at the website provided in “Relevant Websites section”. It takes the raw RNA-seq reads, a genome sequence file, and a transcript annotation file as the input to identify the alternative splicing events corresponding to all major types of alternative splicing patterns and calculates the *P* value and FDR for differential splicing.

FineSplice (2014): FineSplice is a Python wrapped splice junction detection algorithm combined with TopHat2 for a reliable identification of expressed exon junctions from RNA-seq data (Gatto *et al.*, 2014). FineSplice software is freely available at the website provided in “Relevant Websites section”. During the first step, it performs the transcriptome alignment with *de novo* splice junction discovery using TopHat2 with available annotations for known transcript isoforms. The resulting binary alignment map (BAM) file is used as input by FineSplice. At next step, it computes the set of split-read overhangs across each junction for each of the uniquely mapping read. It labels the splice junctions with no matching overhang and defines a potential false positives subset. Then for each junction it constructs a feature vector based on the log₂ deviation. With a defined class label and feature vector, it fits a L1-regularized logistic regression model over the whole set of junctions. FineSplice outputs a confident set of expressed splice junctions with the corresponding read counts. Potential false positives arising from spurious alignments are filtered out via a semi-supervised anomaly detection strategy based on logistic regression. Multiple mapping reads with a unique location after filtering are rescued and reallocated to the most reliable candidate location. This is conjugate approach for an efficient mapping solution with a semi-supervised anomaly detection scheme to filter out false positives. It allows reliable estimation of expressed junctions from the alignment output.

Splicing Code Prediction

Mutations in the splicing signals (5' splice site, 3' splice site and branch point), splicing silencer and enhancer motifs can affect the proper binding of spliceosome and other RNA binding proteins that changes AS patterns. These changes would lead to altered gene products and several diseases as a consequence. Therefore, it is important to be able to predict splicing codes that potentially affect AS. There are several online bioinformatics tools available for the prediction of splicing code that could be useful to understand human variation on splicing and its consequences in human diseases. These predictions are taking advantage of experimentally binding data of RNA binding proteins such as SR proteins as well as experimentally validated splicing signals sequences. These tools take primary sequence as input and predict the splicing regulatory binding sites, properties of exon/intron such as splice site strength, branch point and other regulatory binding motifs.

Tools for Splice Code Prediction: Table 1 summarizes some of such online bioinformatics tools, like Human Splicing Finder (HSF), RegRNA, ESEfinder, Alternative Splice Site Predictor (ASSP), SplicePort, EX-SKIP, RESCUE-ESE, Maxentscan and SROOGLE (Desmet *et al.*, 2009; Huang *et al.*, 2006; Cartegni *et al.*, 2003; Wang and Marin, 2006; Dogan *et al.*, 2007; Raponi *et al.*, 2011; Fairbrother *et al.*, 2004; Eng *et al.*, 2004; Schwartz *et al.*, 2009). Maxentscan (Yeo and Burge, 2004), SplicePort (Dogan *et al.*, 2007), HSF (Desmet *et al.*, 2009) and SFmap (Paz *et al.*, 2010) can be used for the prediction of the basic *cis*-acting elements (5' splice site, 3' splice site and branch point). All these programs provide a useful indication of whether donor, acceptor and branch-point are well defined compared with ideal consensus sequences. ESEfinder and RESCUE-ESE are dedicated to disruption or creation of splicing regulatory elements (SREs) (Cartegni *et al.*, 2003; Fairbrother *et al.*, 2004). In addition, SFmap server is useful to search for the splicing factor binding motifs in the sequence of interest (Paz *et al.*, 2010). RegRNA and SROOGLE are servers can be useful in searching for both basic splicing signals and SREs (Huang *et al.*, 2006; Schwartz *et al.*, 2009). SROOGLE, is one of the most used tools, which provides a graphic output and displays the four core splicing signals with scores based on nine different algorithms. It also highlights the sequences belonging to 13 different groups of SREs. EX-SKIP application compares the ESE/ESS profile of a wild-type and a mutated allele to quickly determine which exonic variant has the highest chance to skip this exon (Raponi *et al.*, 2011).

Performance of Splice Code Predictors: One of the key questions that naturally arises is regarding the performance of these programs for the identification of possible splicing mutations. In humans, SREs tend to be reasonably conserved (Burset *et al.*, 2001) and the programs that evaluate their relative strengths seem to be more successful than those that aim to target the much more loosely conserved SRE elements. MaxEntScan takes the nucleotide dependencies within donor site sequences into account and has been shown to be the best predictors of cryptic splice site activation in disease-causing mutations (Houdayer *et al.*, 2008). Currently, SROOGLE is the most used tool that provides information on splice-sites or enhancer/silencer disruption in a single interface (Schwartz *et al.*, 2009). Some programs such as ESEfinder have worked well in some contexts (Zatkova *et al.*, 2004; Kralovicova and Vorechovsky, 2007; Wang *et al.*, 2005) and have led to a scientific debate in others (Cartegni and Krainer, 2002; Cartegni *et al.*, 2006; Fairbrother *et al.*, 2004; Pfarr *et al.*, 2005; Deburgrave *et al.*, 2007). Combination of all these resources still represents the best chance of “predicting” putative splicing mutations whether in conserved or less conserved regions (Houdayer *et al.*, 2008; Soukariéh *et al.*, 2016). Therefore, it appears that the future trend in developing such prediction algorithms or software will be to integrate all analyses on a single platform. This way, it will be easy to obtain most of the in depth details on global splicing signals on the same platter/platform. Due the progress in this field and improvement in bioinformatics predictions, methodologies related to splicing diagnostics are enticing. In such methodologies, the information obtained from *in silico* bioinformatics approaches are translated to wet lab (*in vitro* and *in vivo*) systems to evaluate splicing efficiencies (Baralle and Buratti, 2017).

Table 1 Online tools for splicing code prediction

<i>Tools</i>	<i>Input</i>	<i>Output</i>	<i>Weblink</i>
Human splicing finder	mRNA sequence	Consensus values of potential splice sites and search for branch points	http://www.umd.be/HSF3/
RegRNA	mRNA sequence	Motifs in mRNA 5'-UTR and 3'-UTR, motifs involved in mRNA splicing, motifs involved in transcriptional regulation, other motifs in mRNA, such as riboswitches, prediction of the splice sites, such as splicing donor/acceptor sites, RNA structural features, such as inverted repeat, and miRNA target sites	http://regrna.mbc.nctu.edu.tw/html/prediction.html
ESEfinder	Exonic sequence	ESE finder use to find the presence of exonic splicing enhancer elements	http://exon.cshl.edu/ESE/
Alternative Splice Site Predictor (ASSP)	Raw sequence, DNA/RNA	Putative alternative exon isoform, cryptic, and constitutive splice sites of internal (coding) exons	http://wangcomputing.com/assp/index.html
SplicePort	Multiple or single sequence	Splice-site predictions and user can also browse feature associated with the prediction	http://spliceport.cbcb.umd.edu
EX-SKIP	Two exonic sequence (up to 4000bp)	It calculates the total number of ESSs, ESEs and their ratio	http://ex-skip.img.cas.cz/
RESCUE-ESE	RNA or DNA Sequence (4 k)	Exonic splicing enhancers (ESEs) prediction	http://genes.mit.edu/burgelab/rescue-ese/
Maxentscan	Each sequence must be the same length	Building distributions over short sequence motifs	http://genes.mit.edu/burgelab/maxent/Xmaxent.html
	5' splice site sequence [3 bases in exon + 6 bases in intron]	5' splice site score	http://genes.mit.edu/burgelab/maxent/Xmaxentscan_scoreseq.html
	3' splice site sequence. [20 bases in the intron + 3 base in the exon]	3' splice site score	http://genes.mit.edu/burgelab/maxent/Xmaxentscan_scoreseq_acc.html
SROOGLE	Exon along with the introns	Graphic display of splicing related data on DNA segments	http://sroogle.tau.ac.il/
SFmap	Human genomic sequence or a list of sequences in FASTA format	Splicing factor binding motifs	http://sfmap.technion.ac.il/

Concluding Remarks

Field of alternative splicing has become very active and attractive in recent years, especially due to the development of high throughput technologies. Consequently, a large number of bioinformatics tools are available for various analyses regarding AS. In fact, it is hard to list every tool developed as of yet, nonetheless, we have reviewed bioinformatics software and algorithms that are used for the detection of splicing events using RNA-seq or other data. Drawbacks or advantages of each approach has been put forth. Some popular online tools and software that can be used to study intronic and exonic mutations leading to splicing defects, have also been discussed.

Biographical Sketch

Praseon Kumar Thakur is presently working as a bioinformatician at the laboratory of RNA Biology at the Institute of Molecular genetics, Prague. He is pursuing a PhD degree in Charles University, Prague, Czech Republic. He has a bachelor's degree in Bioinformatics from the Institute of Advance Studies in Education, Sardarshahr (IASES), India and M.Sc (Bioinformatics) from the Jamia Millia Islamia, New Delhi, India. The focus of his current research is RNA splicing and high-throughput data analysis.

Hukam C. Rawal is presently working as a Research Associate at NRCPB, New Delhi, India. He has over 10 years' experience in different aspects of computational biology. He has good exposure to a wide range of computational approaches for the analysis related to human disease, pathogen infection and crop sciences. He has expertise on advance and popular genomics studies and has worked on different aspects of comparative genomics. He is quite familiar with high throughput sequencing data. He has several publications in the field of comparative genomics, transcriptome assembly, genome level analysis, chloroplast and mitochondrial genome in reputed journals like Genome Biology & Evolution, Genes, Scientific Reports, etc.

Mina Obuca finished her bachelor and master studies in the Faculty of Sciences at the University of Novi Sad, Serbia. Currently, she is a PhD student at the Charles University in Prague, Czech Republic where she is doing her PhD at the Institute of Molecular Genetics in the Laboratory of RNA Biology. She is interested in answering why mutations in splicing proteins are causing retinitis pigmentosa.

Sandeep Kaushik is a passionate computational biologist with a wide exposure of computational approaches. Presently, he is presently carrying out his research as an Assistant Researcher (equivalent to Assistant Professor) at 3B's Research Group, University of Minho, Portugal. He has a PhD in Bioinformatics from National Institute of Immunology, New Delhi, India. He has gained a wide exposure on analysis of scientific data ranging from transcriptomic data on mycobacteria and human samples to genomic data from wheat. His research experience and expertise entails molecular dynamics simulations, RNA-sequencing data analysis, *de novo* genome assembly, protein prediction and annotation, database mining, agent-based modeling and simulations. He has a cumulative experience of more than 10 years of programming (using PERL, R and NetLogo languages). He has published his research in reputed international journals like Molecular Cell, Biomaterials, Biophysical Journal and others.

Genome-Wide Association Studies

Glossary

Common disease/common variant hypothesis The concept that genetic susceptibility to diseases common in a population is likely due to genetic variation that is also common in that population.

Direct association An association between a trait and SNP that is directly genotyped in a study and itself induces an influential biological change.

False positive A result that is statistically significant when the null hypothesis is true.

Genome-wide significance A significance threshold used to account for multiple hypothesis tests conducted in a GWAS which corresponds to the number of effective independent regions in the human genome.

Genotype imputation The use of population-based genome reference panels to infer the state of ungenotyped variants from GWAS data.

Indirect association An association between a trait and a SNP that is in linkage disequilibrium with another nearby SNP that induces an influential biological change.

Linkage disequilibrium The genetic correlation among alleles of co-located SNPs within the genome that is due to

limited recombination events between those SNPs within a population.

Manhattan plot A plot illustrating the magnitude and genomic location of GWAS associations.

Meta-analysis An approach for combining the results of multiple independent studies by analyzing summary statistics.

Population stratification An effect where many SNPs within a study are systematically associated with a trait due to differences in both allele frequency and trait distribution across genetic ancestries.

P-value The probability of observing a value as extreme or more extreme than the test statistic when the null hypothesis is true.

QQ-plot A diagnostic plot used in GWAS to identify systematic inflation of test statistics across all SNPs.

Single nucleotide polymorphism A single base-pair change to the DNA sequence that is common within a population.

TagSNPs A SNP that is used to predict the state of other nearby SNPs via linkage disequilibrium.

Introduction: The Common Disease-Common Variant Hypothesis

Early successes in human genetics led to the discovery of disease genes for a variety of inherited disorders such as cystic fibrosis (Rommens *et al.*, 1989) and Huntington disease (MacDonald *et al.*, 1992). These Mendelian diseases were studied by genotyping families affected by the disease using a collection of genetic markers across the genome, and examining how those genetic markers segregate with the disease across multiple families (Bush and Haines, 2010). This approach, called linkage analysis, was largely unsuccessful when applied to more common disorders, like heart disease, type 2 diabetes, or stroke, implying that the genetic architecture of commonly occurring diseases is likely different from that of rare disorders (Hirschhorn and Daly, 2005). This observation, along with the discovery of some relatively frequent risk alleles for common diseases such as *APOE* alleles for Alzheimer's Disease (Corder *et al.*, 1993) and *PPARG* alleles for type II diabetes (Lander *et al.*, 2000), led to the formalization of a *common disease/common variant* (CD/CV) hypothesis (Reich and Lander, 2001), which simply states that disorders which are common in a population are likely influenced by genetic variation which is also common in that population. To test the CD/CV hypothesis, a new type of population-based study was developed, Genome-Wide Association Studies (GWAS). GWAS was designed to broadly capture common genetic variation, generally defined as DNA base-pair changes with a minor allele frequency (MAF) greater than 5% for the population being studied. Before GWAS could be effectively implemented, however, a catalog of common variation assessed across multiple populations was needed as a reference.

Genetic Variation and Linkage Disequilibrium

Through a large-scale coordinated effort, the International HapMap Project (The International HapMap Project, 2003) captured much of the common variation among 11 human subpopulations, and established the groundwork for GWAS (Manolio *et al.*, 2008). The HapMap Project focused primarily on characterizing *single nucleotide polymorphisms* (SNPs), a single base-pair change to the DNA sequence. The project also produced extensive maps of *linkage disequilibrium* (LD), a property of SNPs that lie on a single chromosome and are co-inherited through the transmission of the chromosome within a population. Humans are diploid, having two copies of each chromosome (with exceptions for X and Y), and recombination events break apart contiguous stretches of SNPs on a chromosome during meiosis when germ cells are created. Through successive generations within a population, repeated recombination events distributed across each chromosome produce stretches of alleles that are correlated to one another. The

degree to which LD exists for a given chromosomal region depends on many factors, including the population size, the number of generations for which the population has existed, the recombination rate, and the number of potential recombination points along the chromosome. The influence of these factors is clear from examining different global populations; African-descent populations on average have smaller regions of LD compared to European-descent or East Asian-descent populations, which were the result of a series of founder events and as a result have larger regions of LD.

Maps of LD were instrumental in the initial design of many fluorescence-based genotyping arrays, which relied on the use of *tagSNPs*, specific variants that were highly correlated (and predictive of) other nearby sites. The use of tagSNPs prevented genotyping SNPs that essentially provide redundant information, and allowed the capture of greater than 80% of all common SNPs in Europeans using 500,000 to 1 Million SNPs from across the genome (Li *et al.*, 2008). Notably, as LD patterns are population-dependent, early genotyping arrays were potentially biased toward European-descent populations as different tagSNPs were needed for optimal capture of variation in other populations.

While tagSNPs greatly improved the capture of genetic information, they also limit any causal inference that can be made from GWAS. When a tagSNP is associated to a disease, this association can either be a *direct association*, where the genotyped tagSNP is the true variant inducing a functional effect, or it may be an *indirect association*, where the true disease-associated variant is in high LD with the genotyped tagSNP. As a result, significant SNP associations from GWAS are not always the true functional/causal variant, and additional fine-mapping studies may be necessary to elucidate the true disease variant.

GWAS Experimental Designs

A critical first step for any genetic study is to precisely define the trait or outcome thought to be influenced by genetic variation. Though there are some exceptions, GWAS generally examine either case/control or continuous outcomes. Continuous, quantitative traits are often preferred as they increase statistical power to detect a genetic effect, and provide a unit change per risk allele. Quantitative traits such as body mass index (BMI) and low-density lipoprotein (LDL) levels are routinely collected through standardized procedures and represent intermediate outcomes for more severe conditions such as heart disease. However, quantitative traits are not always easy to define or collect for certain disorders. For these conditions, dichotomous or case/control categorical variables are used as the primary outcome. Categorical variables however are more susceptible to problematic definitions of “cases” and “controls”, and often require adjudication by clinical experts. For many conditions, consensus criteria have been established for defining case/control status, such as the McDonald criteria for multiple sclerosis (Polman *et al.*, 2011), or the NINCDS-ADRDA criteria for Alzheimer’s disease (McKhann *et al.*, 1984). These standardized, evidence-based approaches can be uniformly applied by multiple diagnosing clinicians to ensure that consistent phenotype definitions are used for a genetic study.

Standardized criteria for study phenotypes are especially critical for multi-center studies. If different case/control definitions are used at different study sites, a site-based effect may be introduced into the study. Even when standardized criteria are used across all study sites, there may still be variability among how clinicians interpret them to assign case/control status. While generally thought to be more accurate, quantitative traits are also susceptible to bias in measurement. For example, in studies of cataract severity, lens (eye) photography is used to assign cataract cases to one of three grades of lens opacity. These photographs are adjudicated by clinicians whose characterizations of cataract stage may not be consistent. Interrater agreement is often evaluated across multiple grading clinicians to measure phenotype consistency (Chew *et al.*, 2010). Significant disagreement between raters typically indicates that disease criteria are not being uniformly applied or interpreted, and a narrower set of phenotype rules are needed.

Once a phenotype has been selected and standardized for a particular study population, genetic information must be collected on study participants. While DNA can be extracted from any tissue, the most common source of DNA for GWAS is whole blood. An individual blood sample is separated into fractions via centrifugation to isolate the buffy coat, a layer between erythrocytes (which do not contain nuclei or DNA) and plasma. The buffy coat contains white blood cells which are subsequently lysed to capture participant DNA. DNA is then processed via vendor specifications for large-scale genotyping using microarray-based technologies, generally from either Illumina (San Diego, CA) or Affymetrix (Santa Clara, CA). These two technologies have relative strengths and weaknesses (DiStefano and Taverna, 2011), and other approaches exist to measure genetic variation, but are not generally used for primary GWAS data collection.

Statistical Analysis

The primary results for a typical GWAS are generated through systematic statistical evaluation of each genetic variant captured by the genotyping process. As part of conducting the statistical analysis for GWAS, genotype data must be encoded, and different encoding schemes reflect different underlying models of allelic effect, and have implications on the degrees of freedom and statistical power of a test. An allelic encoding assumes that each person in the dataset represents two separate chromosomes, and examines the association of the allele to the phenotype. A genotypic encoding assumes that each person is a distinct observation of a combination of two alleles, and genotypes can further be grouped into specific modes of action such as dominant, recessive, multiplicative, or additive models (Lewis, 2002). While these various encoding schemes exist and are used to different degrees in GWAS, it is common practice to examine additive genotypic models only, as this has the best statistical power to detect a variety of modes of action (Lettre *et al.*, 2007).

After choosing an encoding, each SNP is examined independently for association the study phenotype, and the statistical test employed depends multiple factors, most critically whether the phenotype is a quantitative trait or a case/control outcome. In either case, generalized linear models (GLM) are generally used. In the case of quantitative traits, Analysis of Variance (ANOVA) is used to test the deviation from the null hypothesis that there is no difference between the mean trait value across individuals by genotype. Assumptions of the ANOVA apply, most critically that trait follows a normal distribution and that the variance of the trait is the same across groups (the groups are homoscedastic). Case/control traits are typically analyzed using a variant of GLM, logistic regression, which transforms a linear outcome to a probability using a logit curve. While some early GWAS used contingency table analysis methods, such as a chi-square test, logistic regression is now the preferred approach as it allows for adjustment for other relevant factors and can provide adjusted effect estimates for each allele of a SNP. Logistic regression is a mature approach with well-established interpretations and diagnostic procedures to assess the goodness of model fit and the influence of potential outliers (Hosmer *et al.*, n.d.).

Each SNP-based statistical model should also be adjusted for other factors with established effects on the study trait. This often includes demographic factors (i.e., age, sex), clinical factors (i.e., body mass index, comorbidity status), and design factors (i.e., study site, experimental batch). Adjustment for covariates like these reduces artifacts in the statistical analysis that may differentially inflate the frequency of alleles/genotypes between cases and controls. By far the most common confounding factor in GWAS is population substructure. For nearly any phenotype, there are often known differences in the occurrence rate or prevalence across different racial, ethnic, and geographic backgrounds. Similarly, due to human migration patterns, the founding of new populations, and dramatic changes to population size, allele frequencies are highly variable across human subpopulations. Therefore, if a study collects individuals from cases and controls from different ancestral populations, any systematic differences in allele frequency between the ancestral populations will appear as differences between cases and controls – a phenomenon known as *population stratification*. In GWAS, population stratification is generally assessed by estimating the ancestry of each sample in the dataset using either sample clustering within the STRUCTURE software (Falush *et al.*, 2003), or using principal components implemented in the EIGENSTRAT (Price *et al.*, 2006), GCTA (Yang *et al.*, 2011), and PLINK 1.9 (Chang *et al.*, 2015) software packages. Principal component values can then be used as a covariate in statistical models to adjust for minute degrees of ancestry effects present in the study. Linear mixed models (also known as mixed linear models) are also now commonly used to adjust for stratification due to either population differences or familial relationships, including GCTA (Yang *et al.*, 2011), REACTA (Cebamano *et al.*, 2014), EMMAX (Kang *et al.*, 2010), FaST-LMM (Lippert *et al.*, 2011), GEMMA (Zhou and Stephens, 2012), and GRAMMAR-Gamma (Svishcheva *et al.*, 2012).

For each SNP, a statistical model including the encoded effect of the SNP alleles along with any covariate adjustments is evaluated. The effect (also referred to as the β or coefficient) for the encoded alleles is evaluated (by *T*-test in the case of linear regression or Wald test in the case of logistic regression) to produce a *p*-value corresponding to the significance of the SNP. Assuming a null hypothesis that there is no effect of the SNP on the phenotype, a *p*-value is the probability of observing a test statistic equal to or greater than the statistic reported from the analysis of the SNP in the GWAS data. In effect therefore, very small *p*-values indicate that if there is no real association between the SNP and the phenotype, observing the reported test statistic is extremely unlikely. Statistical tests like the *T*-test or Wald test generally conducted in GWAS are often labeled “significant”, meaning the null hypothesis of no association is rejected, if the *p*-value falls below a pre-defined significance threshold (often referred to as α). For most statistical tests, the α is generally pre-set to 0.05, meaning that for 5% of all statistical tests, the null hypothesis is rejected when it is in fact true – a phenomenon called a *false positive*. This 5% probability of a false positive is relative to a single statistical test, and in the case of GWAS, many thousands or even millions of individual hypothesis tests are conducted with each one having a probability of false positive. As a result, assuming α of 0.05, the cumulative probability of finding one or more false positives over a GWAS is much higher. Put a different way, assume you paint one side of a twenty-sided die red; a single roll of this die is unlikely to show the red side, but if you roll this die 500,000 times, it is extremely likely that you roll the red side at least once. The easiest way to adjust for the multiple statistical comparisons conducted in GWAS is to use a Bonferroni correction. This correction adjusts the alpha value for each statistical test from $\alpha=0.05$ to $\alpha=(0.05/k)$ where *k* is the number of statistical tests conducted. Assuming that there is some degree of linkage disequilibrium and thus correlation among statistical tests of a GWAS, this correction is rather conservative as it assumes completely independent tests. Perhaps the most commonly used approach is to assume a level of *genome-wide significance*, which is an estimate of the effective number of independent genomic regions and thus statistical tests for which the analysis should be corrected. This assessment is population specific, owing to differences in LD patterns among different ancestral populations, but in the case of European-descent studies, the genome-wide significance threshold has been estimated at $7.2e-8$ (Dudbridge and Gusnanto, 2008).

There are two commonly used data visualizations shown in GWAS publications, a quantile-quantile (QQ) plot, and a “Manhattan” plot, both implemented in the *qqman* R package (Turner, 2014). A QQ plot (Fig. 1) is a comparison of the *p*-value distribution across all evaluated SNPs to an expected theoretical uniform distribution. Values are typically plotted as the negative log (base 10) of the *p*-values, which provides a unit increase per order of magnitude decrease in the *p*-value (a value of 7 is equivalent to 1×10^{-7}). A QQ plot of log *p*-values is an easy way to visually identify systematic deviations from the null hypothesis – an indicator that other factors like population stratification produce systematic biases across all test statistics. In some cases, the deviation of observed *p*-values from the expected uniform distribution is quantified as a *genomic inflation factor*. A Manhattan plot (Fig. 2) is a similar visualization, showing the negative log *p*-value plotted by chromosome position. These plots often color-code chromosomes on the X-axis to help identify where significant SNPs lie in the genome. A Manhattan plot illustrates two properties of GWAS results, first the physical location of SNPs with extreme *p*-values, and secondly the degree to which a SNP association is corroborated by other nearby SNPs in linkage disequilibrium. Often these plots are labeled with additional information, such as a line demarking the statistical significance criteria used for the analysis, and previously established true positive SNP associations.

Fig. 1 A quantile-quantile plot of GWAS p-values. The negative log10 p-values for each analyzed SNP are plotted on the y-axis versus the expected p-values under the null hypothesis of no associated SNPs on the x-axis. Points deviating from the diagonal line are more significant than expected under the null hypothesis.

The vast majority of published GWAS were conducted using PLINK ([Chang et al., 2015](#); [Purcell et al., 2007](#)) software for statistical analysis. PLINK has numerous functions for conducting genotype and sample quality control, and for performing basic analyses of continuous and binary traits. As the number of genetic variants analyzed in GWAS studies have grown, genetic datasets are often split (by chromosome or other metrics) to facilitate more rapid processing. Analyzing data subsets, however, requires more detailed file and process management, and can introduce errors. To address these issues, software such as HAIL ([Hail, n.d.](#)) has been developed to enable distributed genomic data processing. HAIL provides much of the functionality of PLINK, but performs its operations over a HADOOP/SPARK distributed computing environment. By leveraging this memory and process rich environment, an entire GWAS analysis can be completed in minutes.

Meta-Analysis, Replication, and GWAS Follow-Up

Shortly after initial publications of GWAS for many traits, there was a growing realization within the genomics community that ever larger sample sizes are needed to improve statistical power for the detection of new risk variants. To reduce the need to share individual-level genomic data, research groups began to combine the statistical results from multiple independent GWAS through *meta-analysis*. Techniques for meta-analysis were originally developed to summarize statistical results from multiple independent published studies which examined the same hypothesis. When applied to GWAS, these approaches allow for multiple sets of genome-wide statistical results to be combined using sample size based or inverse variance based approaches as implemented in the software METAL ([Sanna et al., 2008](#); [Willer et al., 2008](#)), or the *metafor* R package, among others. GWAS meta-analysis can be challenging in practice. The multiple studies participating in a meta-analysis must take care to conduct their quality control procedures in a standardized way, include consistent covariate adjustments, and ensure that all statistical results are reported relative to a pre-defined reference allele for each SNP ([Zeggini and Ioannidis, 2009](#)). Even with standardization across studies, there is often some degree to which studies differ, including some planned differences in design and analysis. Heterogeneity across multiple studies participating in a GWAS meta-analysis is often assessed using either the Q statistic or the I^2 index ([Huedo-Medina et al., 2006](#)), with I^2 typically favored as it represents the approximate proportion of variability in a SNP coefficient attributed to heterogeneity between studies ([Higgins, 2008](#)). High degrees of heterogeneity may point to specific outlier studies that may be excluded for legitimate reasons, but may also simply point to unstable associations for a given SNP.

Fig. 2 GWAS Manhattan Plot. The y-axis represents the negative log10 of the p-value for each analyzed SNP. The x-axis illustrates the chromosome (note color coding) and position of each SNP. Horizontal lines mark different levels of statistical significance.

Meta-analyses of GWAS require estimates of consistent alleles from a consistent set of SNPs. In reality, different GWAS often use different genotyping platforms and technologies, leading to different collections of genotyped SNPs for each study. To resolve this issue, studies perform *genotype imputation*, which exploits known patterns of linkage disequilibrium from a selected reference panel to estimate the alleles of ungenotyped SNPs (Li *et al.*, 2009). Popular algorithms for genotype imputation include BimBam (Guan and Stephens, 2008), IMPUTE (Howie *et al.*, 2009), MaCH (Biernacka *et al.*, 2009), and Beagle (Browning and Browning, 2009). Genotype imputation produces an estimate for the allele state at each ungenotyped SNP for each individual, often reported as the probability of each possible allele. Allele probabilities for imputed SNPs should be used in the GWAS analysis to take into account the uncertainty of the genotype imputation process (Marchini *et al.*, 2007). Also, as with other GWAS design factors, population ancestry is of critical importance; the reference panel used in the imputation process must contain individuals drawn from the same population as the GWAS dataset.

Once a key set of SNP-trait associations are discovered from a GWAS, the next critical step is to replicate these associations in an additional independent sample (Chanock *et al.*, 2007). A well-designed replication study should have a sample size to detect the predicted effect of any discovered SNP – ideally large enough to detect an effect slightly smaller than the original (Zollner and Pritchard, 2007). Replication studies should be drawn from the same population as the original GWAS to confirm the effect within the target population. Studies in additional populations are sometimes conducted to determine if the effect of a SNP “generalizes” to other populations (Carlson *et al.*, 2013). Replication studies should use identical phenotype criteria to ensure a clear interpretation of the genetic results. Finally, analyses of replication datasets should show a similar magnitude and direction of effect across both studies.

Conclusions

Genome-wide association studies have played a critical role in identifying thousands of new SNP-trait associations. GWAS as a study design is sometimes considered as both a success and a failure. They are a failure in that even though tens or hundreds of SNPs associate to any given common disease, the collective effect of these SNPs explain very little of the disease risk that is known to be genetic (Maher, 2008). They are a success in that for many diseases, entirely new biological mechanisms of disease have been elucidated for common diseases which have long had little genetic understanding (Hirschhorn, 2009). While many large-scale GWAS have been conducted on many thousands of samples, ever larger studies, coupled with decreasing costs of genotyping and sequencing will likely yield an even better understanding of the genomics of human disease.

Gene Mapping

Kelly L Williams, Macquarie University, Sydney, NSW, Australia

© 2019 Elsevier Inc. All rights reserved.

Introduction

Gene mapping is the sequential allocation of loci to a relative position on a chromosome. Genetic maps are species-specific and comprised of genomic markers and/or genes and the genetic distance between each marker. These distances are calculated based on the frequency of chromosome crossovers occurring during meiosis, and not on their physical location on the chromosome. There are existing dense genetic marker maps available for humans, and the introduction of next-generation sequencing technologies is facilitating increased construction of genetic maps for other species. Genetic maps are a necessary tool for mapping of disease genes or trait loci, a method also commonly known as linkage mapping. Integrating genetic mapping and disease gene mapping with next-generation sequencing has proven to be a powerful strategy in genetic research.

From Meiosis to centiMorgans

Observation of the frequent co-inheritance of traits in *Drosophila* led Morgan, one of the pioneers of genetic research, to first describe the concept of linkage in 1911 as “associations of factors” that are located near together in the chromosomes” (Morgan, 1911). Morgan’s student Sturtevant, another pioneer in genetic research, extended these observations and determined that the proportion of recombinant gametes resulting from crossovers during meiosis allows for the calculation of genetic distance between two loci in *Drosophila* (Sturtevant, 1913). Chromosomal crossing-over is the biological phenomenon occurring during meiosis that underpins genetic variation in populations. No two gametes produced during meiosis are the same. In the process of meiosis, the paternal and maternal inherited chromosomes replicate to form sister chromatids. During prophase I, homologous chromosomes are paired in the cell. Then, two non-sister chromatids undergo recombination (or ‘crossing-over’) where homologous portions of the chromatids exchange places. This results in recombinant chromatids (which are a combination of the maternal and paternal chromosomes) and non-recombinant chromatids (identical to the parental chromosomes) per chromosome (Fig. 1). The recombination fraction (θ) is the probability of a crossing over event occurring between two loci. Crossovers occur semi-randomly throughout the genome and thus allow genetic maps to be constructed.

Genetic distance between two loci is measured in Morgans (M) and is the expected number of crossovers to occur between those two loci on a chromosome in a gamete. A centiMorgan (cM) is a more commonly used measure of distance and corresponds to $\frac{1}{100}$ of a Morgan. Based on Sturtevant’s seminal work, if two loci are unlinked (for example on difference chromosomes), we would expect to see 50% recombinant gametes, and 50% non-recombinant gametes. However if we see lower percentage of recombinant gametes that differs to the expected, such as 13% recombinants, the two loci are considered linked at a genetic distance of 13 cM. One cM roughly corresponds to 1 Mb (1 megabase, or 1,000,000 base pairs), but differs substantially throughout the genome. Recombination rate can vary from 0.1 cM Mb⁻¹ to 3 cM Mb⁻¹ across a chromosome (Kong et al., 2002). Females display a higher crossover frequency than males, therefore the human female genetic map is approximately 44 Morgans, compared to 27 Morgans for males (Broman et al., 1998; Table 1). Dense genetic maps are usually released in three versions: male, female and sex-averaged. Table 1 outlines the map distances and physical distance of each chromosome.

Evolution of Genetic Markers and Human Genetic Maps

The Human Genome Project represented a time of enormous progress in human genetics, and resulted in the construction of dense genetic maps that are still in use by geneticists today. Prior to the publication of the first draft human genome sequence completed under the Human Genome Project, all genetic maps were constructed without having a reference genome sequence. Simply determining the order of genetic markers was a considerable and time-consuming task. The first genetic map of the human genome comprised 403 polymorphic markers, the majority of which were low-informative bi-allelic RFLPs (restriction fragment

Fig. 1 Crossing over between sister chromatids of the same chromosome. Alleles at three loci (A, B and C) are shown. There is a single recombination event between B and C. The parental BC and bc haplotypes will become Bc or bC in the recombinant gametes.

Table 1 Chromosome lengths in terms of Sex-Averaged, Female and Male genetic distances and physical distances

Chromosome	Marshfield map length (cM)			Physical length (Mb)
	Sex-averaged	Female	Male	GRCh38
1	290	365	216	249
2	269	331	209	242
3	228	270	190	198
4	212	264	160	190

length polymorphisms), with an average resolution of 10 cM (Donis-Keller *et al.*, 1987). When microsatellites were identified in the genome, these became the genotyping tool of choice by geneticists, as they were multi-allelic and therefore highly heterozygous in the population (Litt and Luty, 1989; Weber and May, 1989). These polymorphic short tandem repeat sequences, usually di-, tri- or tetra-nucleotide repeats, are able to be amplified by PCR and therefore less cumbersome to genotype when compared to RFLPs. Their prevalence throughout the genome, and informativeness for recombination, led to the construction of the first dense human genetic maps, some of which are still in use today. The Marshfield genetic map (see “Relevant Websites section”) provided the first complete genome-wide comprehensive genetic map comprising more than 8000 microsatellite markers, including heterozygosity values for each marker (Broman *et al.*, 1998). Once the first draft of the human genome sequence was released, geneticists began to construct denser microsatellite marker genetic maps in a comparatively shorter period of time (Kong *et al.*, 2002). Comprehensive sequencing of the human genome identified an increasing number of bi-allelic single nucleotide polymorphisms (SNPs), which would ultimately become the next genetic marker of choice. SNPs are less informative than microsatellites (they only have a maximum heterozygosity of 0.5), but their abundance throughout the human genome has allowed for construction of very dense genetic maps. Due to their bi-allelic nature, hundreds of thousands of SNPs can be genotyped on a microarray in parallel with a small input volume of DNA. The next major human genetic map to be published was the deCODE genetic map in 2010 (Kong *et al.*, 2010). In contrast to previous microsatellite marker genetic maps, the deCODE genetic map comprises 300,000 less informative bi-allelic SNPs, but at a higher density to get resolution to 10 kb.

With the publication of the first reference human genome (Lander *et al.*, 2001; Venter *et al.* 2001) and the public repository of genetic mapping data, combined genetic-physical maps were able to be constructed (Kong *et al.*, 2004; Matise *et al.*, 2007). These maps are able to be used for interpolation of genetic map positions of unmapped markers or genomic variants. Web-based interpolation tools exist (such as that at Rutgers: see “Relevant Websites section”), or scripts from Github Repository for interpolation on a larger scale (an example python script: see “Relevant Websites section”). Interpolation of genetic maps (see Section Using Interpolated Genetic Maps for Shared IBD Segment Analysis below) is now particularly relevant with whole-genome sequencing datasets available with genotypes at each nucleotide position in the genome.

Generating a Genetic Map

Construction of genetic marker maps begins with a small set of loci, with the gradual addition of more loci. Somatic cell genetics and cytogenetics was used in the 1970s to first assign genetic markers to specific regions on single chromosomes. New genetic

markers, whether RFLPs, microsatellites or SNPs, are then genotyped in large families and recombination fractions are determined. As part of the Human Genome Project, DNA samples from the CEPH Reference Family Panel was used collaboratively worldwide for genotyping for the construction of genetic maps (Dausset *et al.*, 1990). CEPH Reference Family Panel DNA samples that were made available to the genetics community, allowed standardised genotyping by using a common set of families. Using observed recombination fractions from genotyping data, there are established software tools to construct a genetic map including LINKMAP (Lathrop *et al.*, 1984), MAPMAKER (Lander and Green, 1987; Lander *et al.*, 1987) and CRI-MAP (P. Green, K. Falls, and S. Crooks, documentation for CRI-MAP, version 2.4). These tools utilise map functions, which are mathematical relationships that transform non-additive recombination fractions (θ) into additive map distances (x). The most commonly used transformations are Haldane's and Kosambi's mapping functions (Haldane, 1919; Kosambi, 1944), both of which are still used by geneticists for mapping genomes. To calculate genetic distances (x) from recombination fractions (θ):

$$x = -1/2 \ln(1 - 2\theta) \quad \text{Haldane's map function}$$

$$x = 1/4 \ln \frac{1 + 2\theta}{1 - 2\theta} \quad \text{Kosambi's map function}$$

The mapping function that Kosambi derived assumes genetic interference, whereas the Haldane-derived mapping function does not allow for genetic interference. Genetic interference is the reduction in randomness of crossovers on a chromosome due to a decreased likelihood of a new crossover in the immediate vicinity of an existing crossover. Conversions between θ and x using several map functions can be performed interactively using the MAPFUN linkage utility program (see "Relevant Websites section"). Nonetheless, with today's dense human genetic maps, there is little need for mapping functions.

However in plant and animal genetics, construction of genetic maps of rare species is still an active field of research, and will be outlined below in Section Gene Mapping in Plants and Animals.

Linkage Analysis for Mapping Mendelian Disease Genes

When elucidating the cause of a Mendelian disease, identifying the causal gene would be considered the most important aspect of the research. Pinpointing the approximate location of the disease locus on a genetic map is the first step in identifying the causal gene. Subsequent fine mapping using additional genetic markers, and then sequencing of gene exons contained within the linkage region to find a mutation, is performed. Once a causal gene is identified, the mechanisms by which the mutation, and therefore mutated gene, causes disease is able to be further investigated. Identifying disease genes through linkage mapping offers the clinical potential for diagnostic tests and treatment.

Linkage Simulation and Genotyping Prior to Analysis

Disease gene mapping differs to constructing a genetic map of markers, as disease loci are mapped based on genotypes from families specifically collected for the study. Historically, to successfully identify a locus significantly linked to disease, a large multigenerational family with many DNA samples from both affected and unaffected individuals was required. Prior to generating genotype data, geneticists commonly perform a computer simulation on the family of interest. SLINK (Ott, 1989; Weeks *et al.*, 1990) and SIMLINK (Boehnke, 1986; Ploughman and Boehnke, 1989) are examples of such simulation software and require input data including pedigree, number of genetic markers used in the study, allele frequencies, recombination fractions between loci, mode of inheritance and disease penetrance. This prospective analysis can determine the statistical power of the proposed linkage study, and therefore the suitability of the family to conduct a linkage study.

DNA samples are then collected from available family members, including both individuals affected with the disease of interest and those unaffected. Extensive genotyping is then performed on the family members using either microsatellite markers or SNP microarrays, or a combination of both. Current SNP microarrays can genotype 500,000 – 2 million SNPs on a single chip. Although the density of markers is significantly greater when using SNP microarrays, they are less informative, frequently occur in LD (linkage disequilibrium) and have a maximum heterozygosity of 0.5. Since multiallelic microsatellite markers are highly informative due to their heterozygosity (which can be as high as 0.95), less markers are required for a comparable amount of linkage information (Dunn *et al.*, 2005). Genotype data and pedigree information is then converted into input files for linkage programs.

Linkage Programs and Lod Scores

The statistical measure of linkage for a disease locus is known as a lod score (or logarithm of the odds) and was first defined by Morton (1955). A lod score $z(x)$ is the logarithm (base 10) of the likelihood ratio: The likelihood of the data if the disease locus is linked to the genetic marker and the likelihood of the data if the disease locus is unlinked to the marker, where x represents a particular value of recombination fraction $0 \leq \theta \leq 1/2$:

$$z(x) = \log_{10} \left[\frac{L(\text{pedigree if linked, } \theta = x)}{L(\text{pedigree if unlinked, } \theta = 0.5)} \right]$$

Fig. 2 Pedigree showing segregation of an autosomal dominant trait and a phase-known genetic marker. Recombinants (R) and non-recombinants (NR) between the trait locus and the marker locus are shown.

A lod score is a function of θ in the range of $0 \leq \theta \leq 1/2$ that always has a value of 0 at $\theta = 1/2$. The maximum of the lod score function occurs at the maximum likelihood estimate to θ . In the example pedigree in Fig. 2, the likelihood of observing linkage data is:

$$L = \theta^R (1 - \theta^{NR})$$

where θ is the recombination fraction, R is the number of recombinants and NR is the number of non-recombinants at a specific genetic marker. The likelihood of not observing linkage is

$$L = (0.5)^{(R+NR)}$$

Since grandparent genotypes are available this pedigree is considered phase-known, and therefore there is 1 recombinant and 5 non-recombinants in this pedigree. To calculate a two-point lod score at a range of recombination fractions is as follows:

$$z(\theta) = \log_{10} \left[\frac{(\theta)^1 (1 - \theta)^5}{(0.5)^6} \right]$$

$$z(x) = \log_{10} \left[\frac{0.5(\theta^1 (1 - \theta)^5) + 0.5(\theta^5 (1 - \theta)^1)}{(0.5)^6} \right]$$

At $\theta = 0.01, 0.05, 0.1, 0.2, 0.3$, and 0.4 , the calculated lod scores are $-0.22, 0.40, 0.58, 0.62, 0.51$, and 0.30 . However, if the pedigree only has genotype information in one or two generations, the pedigree is considered phase-unknown, and this must be taken into consideration in lod score calculations. Consider the example pedigree in Fig. 3 where there are two possible phases. Phase 1 has 1 recombinant and 5 non-recombinants, whereas Phase 2 has 5 recombinants and 1 non-recombinant. To calculate lod scores for this example, both phases need to be considered:

At $\theta = 0.01, 0.05, 0.1, 0.2, 0.3$, and 0.4 , the calculated lod scores are $-0.51, 0.09, 0.28, 0.32, 0.22$, and 0.08 . Calculating lod scores by hand is a very laborious task. A ground-breaking development in human genetics studies was the development of LIPED, the first generally available computer program to perform linkage analysis, thus computational calculation of lod scores (Ott, 1974, 1976). LIPED is based on the Elston-Stewart algorithm (Elston and Stewart, 1971) and is restricted to two-point linkage analysis, which is pairwise comparisons between a disease (or trait) locus and each marker locus. Linkage programs output lod scores for each marker at different recombination fractions (such as the example for Arts Syndrome in Table 2), and can also include the exact recombination fraction where the lod score is at a maximum ($Z_{\max}$).

Fig. 3 Pedigree showing segregation of an autosomal dominant trait and a phase-unknown genetic marker. Recombinants (R) and non-recombinants (NR) between the trait locus and the marker locus are shown for the two different haplotype phases.

Table 2 Pairwise lod scores of Arts Disease and markers at Xq21.33 – Xq24. The descending order of markers is proximal to distal. The underlying disease gene was found to be *PRPS1* and maps to proximal of marker DXS1105.

Marker	Locus	$\theta = 0.00$	$\theta = 0.10$	$\theta = 0.20$	$\theta = 0.30$	$\theta = 0.40$
DXS1231	Xq21.33–q22.1	$-\infty$	-1.00	-0.33	-0.06	0.03
DXS178	Xq22.1	3.69	2.98	2.26	1.53	0.78
DXS1106	Xq22.2	6.97	5.57	4.08	2.53	1.06
DXS1105	Xq22.3	6.84	5.45	3.94	2.35	0.85
COL4A5	Xq22.3	5.38	4.18	2.95	1.78	0.76
DXS456	Xq22.3–q23	5.77	4.36	2.96	1.73	0.70
DXS424	Xq23	4.23	3.57	4.24	1.99	1.05
DXS1001	Xq24	$-\infty$	2.01	1.97	1.47	0.76

Note: Modified from Kremer, H., Hamel, B.C., van den Helm, B., *et al.*, 1996. Localization of the gene (or genes) for a syndrome with X-linked mental retardation, ataxia, weakness, hearing impairment, loss of vision and a fatal course in early childhood. *Human genetics* 98, 513–517 and de Brouwer, A.P.M., Williams, K.L., Duley, J.A., *et al.*, 2007. 'Arts syndrome is caused by loss-of-function mutations in *PRPS1*'. *American Journal of Human Genetics* 81, 507–518.

Since lod scores can be additive across families with an identical disease, two-point lod scores were historically reported at the following fixed set of θ values: 0, 0.01, 0.05, 0.1, 0.2, 0.3 and 0.4 (Conneally *et al.*, 1985). Lod scores (or sums of lod scores) of 3.0 or more are indicative of genome-wide significant evidence for linkage corrected for multiple testing (or greater than 2.0 on the X chromosome), whereas lod scores of less than -2.0 indicate non-linkage and can be used for exclusion purposes (Morton, 1955). Lod scores between -2.0 and 3.0 are inconclusive and require additional families, and thus more linkage analysis to be performed. Lander and Kruglyak (Lander and Kruglyak, 1995) built on Morton's work to determine that a more statistically accurate genome-wide significant lod score would be 3.3, and that a lod score of 1.86 is evidence of suggestive linkage.

The LIPED program was subsequently extended to provide multipoint analysis, resulting in the suite of LINKAGE programs for Linux and Windows ("see Relevant Websites section"), which are still in use today (Lathrop *et al.*, 1984). Dense genetic marker maps have made multipoint analysis possible, where simultaneous analysis of several linked loci is performed. Other multipoint linkage analysis programs are outlined in Table 3. In multipoint linkage analysis studies, geneticists will evaluate whether to apply parametric or non-parametric multipoint linkage analysis. Parametric multipoint analysis is usually applied to a few large pedigrees that have a known (or assumed) mode of inheritance of a disease or trait. A 'parameter' is set during linkage analysis: An explicit model of inheritance specifying the relationship between genotype and disease/trait. Parametric multipoint analysis is to identify linkage between the disease/trait gene and markers on the genetic map. In comparison, non-parametric multipoint analysis does not consider inheritance of the disease/trait. This analysis is usually considered an 'allele sharing' method that can look at many small families with the same disease.

Limitations of Current Linkage Analysis Programs

Although the introduction of computerised calculation of lod scores provided a platform for geneticists to regularly perform disease gene mapping studies, linkage programs have computational limitations. Improvement and enhancement in the algorithms over recent decades has improved efficiency of the programs, but computational burden is the major limitation, and is an ongoing problem with the current linkage programs in Table 3. Computational complexity increases with an increasing number of genetic markers or pedigree individuals. The Elston–Stewart algorithm (Elston and Stewart, 1971), which is used by LINKAGE and

Table 3 Multipoint linkage analysis software

Program	Multipoint analysis	Algorithm	Reference
LINKAGE	Parametric	Elston-Stewart	Ott (1974)
FASTLINK	Parametric	Elston-Stewart	Cottingham <i>et al.</i> (1993)
GENHUNTER	Parametric and Non-parametric	Lander-Green	Kruglyak <i>et al.</i> (1996)
ALLEGRO ^a	Parametric and Non-parametric	Lander-Green	Gudbjartsson <i>et al.</i> (2000)
MERLIN	Parametric and Non-parametric	Lander-Green	Abecasis <i>et al.</i> (2002), Abecasis and Wigginton (2005)

^aDeprecated.

FASTLINK programs, scales exponentially with the number of marker loci considered, and generally cannot handle more than 5–10 markers at a time. This is a serious limitation in the current environment where hundreds of thousands of genetic markers can be used per person in linkage analysis. Conversely, GENEHUNTER, ALLEGRO AND MERLIN use the Lander-Green algorithm which uses a hidden Markov model (HMM) to calculate probability distributions of inheritance vectors (Lander and Green, 1987). Computational time and memory requirements only increase linearly with additional markers, but increase exponentially as the number of meioses in a pedigree increases. In addition, there is an upper limit of 32 meioses in a pedigree because of the representation of inheritance vectors as 32-bit integers (Markianos *et al.*, 2001).

To date, there is no widely used linkage analysis program that can handle both large pedigrees and a large number of markers. There is a need for more powerful methods and enhancements to gene-mapping algorithms.

Human Linkage Analysis in the Age of Next-Generation Sequencing

Although linkage mapping for disease gene discovery was largely surpassed by large-scale GWAS studies due to the introduction of SNP microarrays, the era of next-generation sequencing has enabled linkage mapping to be revisited by geneticists. Combining linkage analysis results, with either whole-exome or whole-genome sequencing results has become an extremely powerful tool for identifying disease genes. Fig. 4 outlines standard procedures geneticists use when combining data from these technologies.

In the current genetics/genomics environment, usually smaller families undergo linkage analysis using either microsatellites or SNP microarrays. The main reason for this being that many large families with clear Mendelian inheritance have already undergone linkage analysis in the previous decade, and thus have data already available. Prospective simulation analysis will frequently determine that these smaller families cannot meet genome-wide significance (i.e., a lod score > 3.3), however lod scores of < -2.0 can exclude large regions of the genome that will not harbour the causal mutation. DNA from all available family members will undergo linkage analysis, however due to higher costs, only a few informative individuals from the pedigree will undergo next-generation sequencing.

Standard bioinformatic workflows applied to raw next-generation sequencing data results in a VCF file, comprised of all identified variants in the entire genome. These bioinformatic workflows are covered in detail in the Next generation sequence analysis Reference Module. With genomic variant data, instead of geneticists spending years of research performing laborious Sanger sequencing for every exon in every gene in each linked region, next-generation sequencing provides a list of all the variants present in a comparably short period of time (often weeks). For example, a recent gene discovery publication for a large autosomal dominant amyotrophic lateral sclerosis/frontotemporal dementia family used genome-wide microsatellite linkage analysis from all available family members combined with exome sequencing data from four affected individuals within the family. Linkage analysis pinpointed the disease gene to a 7.5 Mb linked region on chromosome 16, containing more than 100 genes comprised of over 2000 exons. A considerable effort, and cost, would be required to Sanger sequence each of these exons. In a demonstration of the power of this combined technique, whole-exome sequencing and standardised filtering of the VCF (unshared variants, MAF > 0.001 in public databases) identified only a single non-synonymous mutation in the linkage region, in the *CCNF* gene. Subsequent Sanger sequencing of this gene in all family members demonstrated strong segregation of the mutation with disease (Williams *et al.*, 2016).

Using Interpolated Genetic Maps for Shared IBD Segment Analysis

Linkage maps are not only used for disease gene mapping, but can be integrated with other software packages to identify cryptic relatedness within a cohort of interest. Currently programs exist to work with large GWAS cohorts. These programs include PLINK (Purcell *et al.*, 2007) and KING (Manichaikul *et al.*, 2010) which can determine first and second degree relatives. Often, geneticists want to identify these relations to remove them from a study to prevent confounding, biasing or inflating GWAS results. However, these tools are not accurate past 2nd degree relatives. More complex programs exist to identify more distantly related individuals (up to 7th degree) using IBD segment analysis, and can utilise either SNP microarray data or whole-genome sequencing variant files (VCF). First the genotype data needs to be phased using Beagle (Browning and Browning, 2007), usually in comparison to a phased references population. The phased data is compared alongside interpolated genetic maps to discover long shared segments of Identity by Descent (IBD) between pairs of individuals (GERLINE program; Gusev *et al.*, 2009). To then identify cryptic relatedness through shared ancestry, a maximum likelihood method is applied to the IBD segment data, using the number and genetic lengths of IBD segments, for the estimation of recent shared ancestry (ERSA) (Huff *et al.*, 2011).

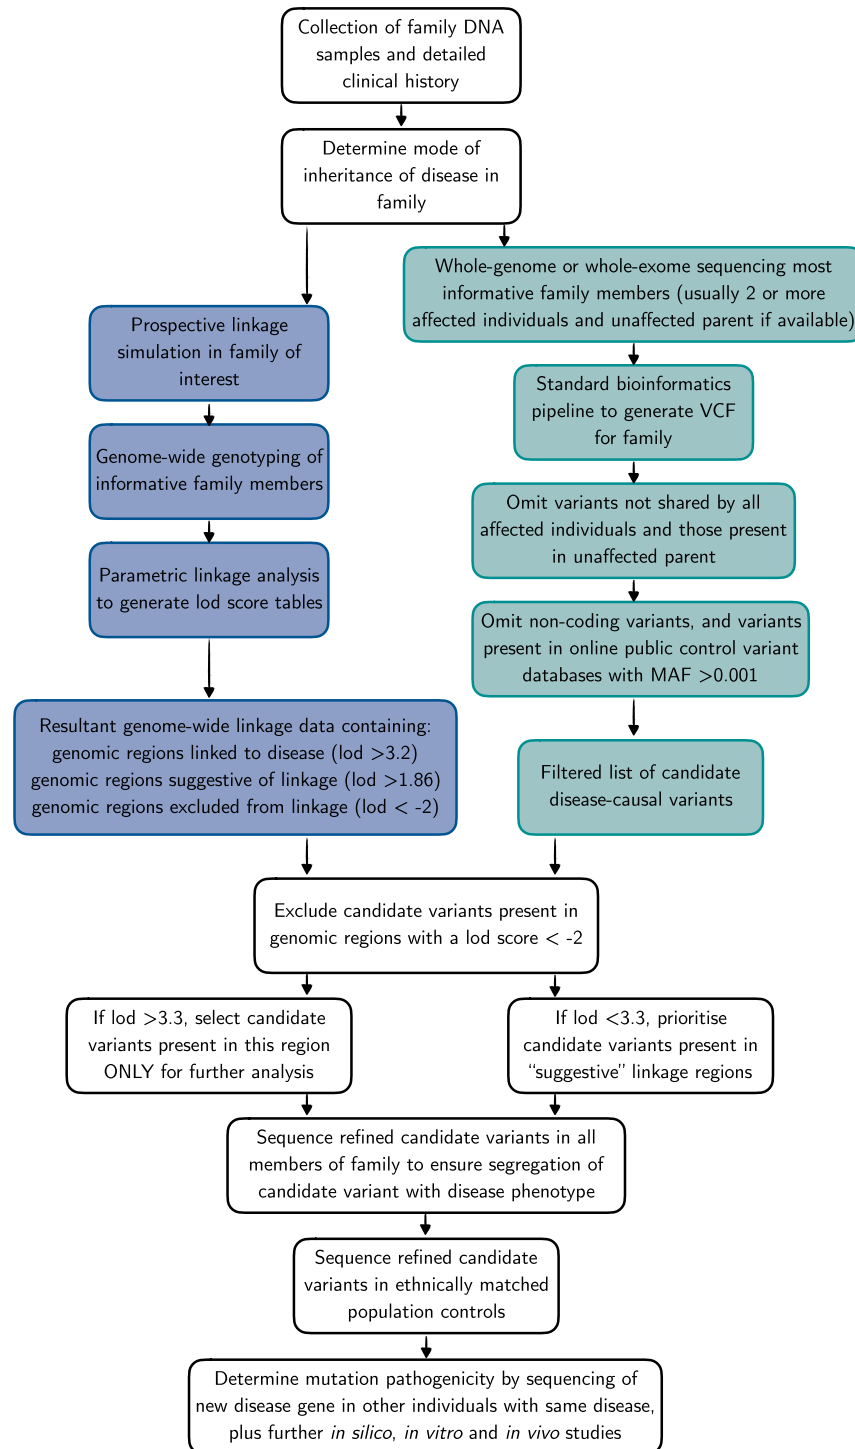

Fig. 4 Workflow for disease gene mapping using a combination of linkage analysis and next-generation sequencing methods. Linkage analysis workflow is outlined in blue, next-generation sequencing workflow is outlined in green, combined analysis is in black.

Gene Mapping in Plants and Animals

Existing human genetic maps are dense, well constructed, highly informative and amenable to interpolation, thus there is a limited need to develop new human genetic maps. Yet in plants and other animals, there is still a strong desire by geneticists to develop genetic maps for their species of interest. In contrast to human gene mapping studies, gene mapping in plants and animals, particularly those with agricultural interests, can be for identification of beneficial traits (quantitative trait loci, QTL). Genetic

markers linked to QTLs are then used for marker-assisted plant selection to expedite genetic improvement in the species. Next-generation sequencing technologies have opened a new article in gene mapping for rare species. Plant and animal geneticists can use whole-genome sequencing to construct draft reference genomes, identify species-specific genetic markers (such as SNPs), and then to use these markers in species-specific genetic maps. Existing genetic maps of similar species can also be used to refine and complete genetic maps of other species. For example, a recently completed genetic map of the Atlantic Salmon was used to improve the genome sequence of the Rainbow Trout (Lien *et al.*, 2016).

One of the major challenges for rare species is that draft reference genomes constructed by *de novo* assemblies are often incomplete and with alignment mistakes in the assembly. *De novo* assembly has good fine-scale accuracy, but poor large-scale accuracy for constructing chromosomes (Fierst, 2015). Geneticists are able to use genetic maps and recombination to resolve these errors by ordering, correctly orientating and concatenating the contigs into chromosomes. New tools coupling *de novo* assembly with linkage mapping provide a powerful method to generate a high-quality reference sequence (Rastas *et al.*, 2013; Liu *et al.*, 2014).

Conclusions

Gene mapping has gone through peaks and troughs over the past several decades. In the 1980s and 1990s, increasing number of publications were reported linking human Mendelian disease genes to loci. The Human Genome Project represented the peak of gene mapping efforts to develop dense gene maps of the human genome containing thousands of informative markers. In the 2000s, these genetic maps were highly used to pinpoint disease loci for more Mendelian disorders. However, for complex diseases, genome-wide association studies (GWAS) using SNP microarrays became increasingly popular. In the last decade, the introduction of next-generation sequencing dramatically decreased the use of linkage mapping in human disease. Instead, geneticists sequence the entire exome or genome of multiple affected individuals and search for shared variants as putative causal mutations. This does not require large families, usually only a few affected individuals in a family. This has proven more fruitful in recessive diseases compared to dominant diseases, and geneticists are beginning to return to use linkage mapping coupled with next-generation sequencing as a powerful approach to identify disease genes. Conversely, animal and plant genetics are thriving by using next-generation sequencing technologies to facilitate generating genetic maps of their chosen species. Prior to next generation sequencing, the cost, time and difficulty in generating a genetic map of a rare species was prohibitive. Now using variant identification following *de novo* assembly, coupled with linkage maps of similar species, an increased number of publications are coming from these fields of research. This has the potential for major impact on agricultural genetics, as high-density linkage maps facilitate mapping quantitative trait loci (QTL) for important traits. The main challenge facing geneticists now is overcoming, or reducing, sequencing errors encountered in next-generation sequencing.

Genome Databases and Browsers

Introduction

"In God we trust. All others must bring data." – W. Edwards Deming

"Data matures like wine, applications like fish." – James Governor

The effective use of genomic data is vital for many different fields, from disease research, to drug development, to biosecurity, to agriculture. Analysing this data lets us determine how organisms function, what causes certain traits and features, and what variation there is between different organisms, both within the same species as well as across species. As ideas and desires such as personalised medicine gain traction, the importance of careful and considered genomic analysis will only increase. However, the field of genomics is growing at an unprecedented rate, spurred on in recent times by the development and improvement of various genomic sequencing techniques. In the 15 years since the completion of the Human Genome Project in 2003, the time, manpower and financial costs of sequencing the genome of an organism have all dramatically decreased. It is therefore no surprise that there has been an explosion of sequencing data on both familiar and novel organisms in the years since. However, while it is of great benefit to science to have such a wealth of data available, it is difficult use effectively without the right tools. Appropriate methods of storing, organising, curating, and accessing the data (in the form of databases), as well as viewing, editing, and analysing the data (in the form of browsers) are vital in progressing the field.

As whole-genome sequencing (WGS) becomes more routine, smaller sequencing projects of specific genes or groups of genes have become even more common. The amount of data that these projects produce needs to be managed effectively, so that it can be stored, accessed and shared among researchers. However, the sheer volume of the data, as well as the number of organisms, data sources, and study types mean that there are thousands of different databases available to access genomic data, depending on what is being sought. Individual research communities will have specific databases that are more useful than others, but there are still a number of common features across them, and a small number of repositories that span multiple organisms.

Being able to access data is an important first step in doing high-quality research (or research at all), but if the data cannot be visualised and analysed effectively, there is little point in accessing it in the first place. This is especially true for genomic data, where its sheer volume coupled with its repetitive nature creates a situation in which annotation and visualisation are vital to making the data have any meaning. Genome browsers have been developed alongside databases to deliver on this requirement. However, like databases, there are many different browsers available with which to analyse data. These largely vary on how robust they are, whether they are server-based or local, and what specialised tools they have embedded in them. In general however, there are a small number of key browsers that tend to be suitable for broad, generic purposes, which have then served as the basis for the development of more specialised browsers and tools.

The current article is divided into four sections. The first section discusses currently available databases for accessing genomic data, including important multi-organism databases, as well as more specialised ones. The second section discusses the state-of-the-art genome browsers available to visualise and analyse genomic data, including their range of different capabilities and specialised tools. The third section uses WormBase as an example database, and visualises data from WormBase using GBrowse as an example of a broad-purpose genome browser. The fourth section discusses the future directions and issues involved in developing genome databases and browsers, and provides further reading to the interested reader.

Fundamentals

Genome Databases

Genomic databases allow for the storing, sharing and comparison of data across research studies, across data types, across individuals and across organisms. These are not a new invention – even before the popularisation of the modern internet, 'online' databases have been available in order to share data on key organisms, such as *Escherichia coli* (Blattner *et al.*, 1997) and *Saccharomyces cerevisiae* (Cherry *et al.*, 2012). Recent advances in both data sharing technology and genome sequencing technology have created an explosion of databases, based around particular organisms, as has been historically the case, as well as around particular data types, such as transcriptional data or short-read sequencing data. This section discusses a number of key classes of genome databases, namely broad cross-organism databases such as NCBI Genome and Ensembl Genome, specific organism

databases and the GMOD project family, and the broad variety of databases available for human genome research. The IDs provided in brackets correspond to those in the ID column of [Table 1](#).

Broad Databases

From the early development of genome databases several decades ago, there have been ongoing efforts to combine and index multiple databases in central repositories for ease of access. With the avalanche of genomic data in the last decade, these efforts have become more difficult. However, there are still two key databases which serve as first-point-of-call references for genomes, especially if the desired genomic information is likely to be accessed by many researchers. These are the NCBI Genome database (1), co-ordinated by the National Centre for Biotechnology Information in the United States, and the Ensembl Genomes database (2), jointly co-ordinated by EMBL-EBI and the Wellcome Trust Sanger Institute in the United Kingdom.

At time of writing, NCBI Genome contains genomic information on 35,211 distinct organisms, which are further indexed as eukaryotes (5413 entries), prokaryotes (134,749 entries), viruses (14,054 entries), plasmids (11,946 entries), and organelles (11,504 entries). These can contain multiple assemblies, and can be downloaded or searched on the database itself through a number of tools.

Ensembl Genomes also acts as a repository of genomic data across multiple kingdoms of organism, and is complemented by five sub-sites: Bacteria-Ensembl, Protist-Ensembl, Fungi-Ensembl, Plants-Ensembl, and Metazoa-Ensembl, containing the genomes of bacteria (50,364 entries), protists (200 entries), fungi (882 entries), plants (55 entries), and invertebrate metazoa (71 entries) respectively. This is in addition to the 12 central Ensembl organisms, including zebrafish (*Danio rerio*), chicken (*Gallus gallus*), human (*Homo sapiens*), and mouse (*Mus musculus*). Ensembl Genomes also allows for data to be downloaded or analysed using online tools. There is also the option to analyse the genomic data in Ensembl, the genome browser associated with the database itself (discussed further below).

Specific Organism Databases and the GMOD Project

It is possibly unsurprising that with the evolution of sequencing technology and the power to sequence the genome of most any organism, given a reasonable amount of time and a reasonable amount of research effort, individual databases have developed around the genomes of specific organisms. In the past, this was mostly focussed around so-called ‘model’ organisms, or ones with large research bases, such as the mouse (*Mus musculus*) ([Smith et al., 2018](#)) and nematode (*Caenorhabditis elegans*) ([Lee et al., 2018](#)). In many cases, these were created by their own research communities, to suit their own needs, both in terms of how the data could be accessed, as well as what tools were provided to dissect the data. As efforts continued, there have been moves to create some consistency between databases and the tools they offer, meaning new organism databases are not required to ‘re-invent the wheel’ so to speak. In this regard, the Generic Model Organism Database (GMOD) project has served to provide a framework of tools and database methods to allow new databases to be created. The ‘users’ of the GMOD project are no longer limited to ‘model’ organisms, and now consist of a variety of different species and databases. The GMOD project also has its own genome browser associated with it, GBrowse (as discussed further below), which can be integrated into the participating databases as a web-based genome browser.

Human Genome Databases

The breadth and depth of human genome databases is vast, as is to be expected when an organism attempts to study itself, and analyse its own biological problems. These databases are often structured around various data sources, such as transcriptional data, as is the case for the H-Invitational database (H-InvDB) (4). Particular study types have also given rise to specific databases: genome-wide association study databases such as GWASCentral (5), and structural variant study databases such as dbVar (6) and DGV (7). As is the case with other organisms, there are also some databases which seek to be more comprehensive in scope: DNA

ENCODE	8	https://www.encodeproject.org/	Sloan et al. (2016)
IGSR (1000 Genomes)	9	http://www.internationalgenome.org/	The Genomes Project Consortium (2015)

element databases such as ENCODE (8), and the 1000 Genomes project database, now hosted as the International Genome Sample Resource (IGSR) (9). Databases for even more specific purposes exist, such as a wealth of databases on cancer genomic data, and will need to be searched for on a case-by-case basis depending on need.

Genome Browsers

Data access and quality means very little if no meaning can be gained from it. In a field with as complex and abstract data as genomics, methods for data visualisation and analysis are of even greater importance. These must be able to cope with vast amounts of data, in the order of gigabytes or terabytes, as well as be able to connect these to tangible, biological meaning in the form of genes and products. Genome browsers seek to fill this need by providing a pre-existing software basis to visualise and analyse genomic data. Due to the sheer variety of researchers, purposes, expectations, and goals involved in the field, a number of genome browsers are available. For the new user, there are three broad-class, easy-to-pick-up databases for generic uses that stand out at present: the UCSC Genome Browser, managed by the University of California, Santa Cruz (Casper *et al.*, 2018); GBrowse, managed by the GMOD project (see “Relevant Website section”); and Ensembl, managed by EMBL-EBI and the Wellcome Trust Sanger Institute (Zerbino *et al.*, 2018). This section will consider each of these browsers in turn, and then give an overview of the more specific browsers which have been created based on these three forerunners.

UCSC Genome Browser

UCSC Genome Browser is the one of the most widely regarded broad-class browser, and has been integrated into a number of major databases. Its initial conception in 2000 was to visualise the first working draft of the Human Genome Project, but has been adapted in the following years to include a broad variety of organisms, and a vast suite of tools for visualising and analysing data.

Gbrowse

Due to the ‘generic’ nature of the GMOD project (discussed above at 2.2), there was a need for a generic browser to accompany the suite of tools provided for new databases. GBrowse developed from this idea, and is therefore one of the more flexible genome browsers available. It has had a number of spin-off browsers created since its conception, tailored for particular purposes. As it is a part of the GMOD project, it is also available across many different databases.

Ensembl

The Ensembl genome browser created by EMBL-EBI and the Wellcome Trust Sanger Institute is the native genome browser for the Ensembl Genomes databases. Due to the broad nature of the databases it is used for, it contains a broad variety of tools for visualisation and analysis across a variety of kingdoms of organisms.

Specialised Browsers

Browsers for more specialised purposes have been developed by particular groups, largely based on one of the primary three browsers. Due to its generic nature, the majority of ‘subsidiary’ browsers are based on GBrowse in particular. Lighter implementations have been created, such as JBrowse, as well as browsers more suited to collaboration and annotation, such as Apollo.

Applications

Wormbase and GBrowse

An illustrative example of a user-friendly genome database, as well as a common all-purpose genome browser, is the WormBase-GBrowse pairing. WormBase (Lee *et al.*, 2018) is a member of the GMOD family, meaning it has the GBrowse genome browser embedded in the site. This makes quick searches extremely easy, and allows for visualisation of data before download.

The basic functionality of WormBase is illustrated in Fig. 1, through the homepage, search, and GBrowse features. The homepage is very user-friendly with logical menus and news items. The search function allows the user to access gene information across a variety of species, including *C. elegans*, *C. briggsae*, and *C. brenneri*. It also allows for search by class of information, including gene, strain, protein, or sequence feature. Searching for a particular gene gives the option to open the gene in GBrowse, as shown in Fig. 1(c) for the *set-23* gene in *C. elegans*. The *set-23* gene has been shown to be an embryonic lethal gene, and as such could be a possible CRISPR target in the future – knowing the location (chromosome IV), length (2625 bp), and protein coding regions (as shown in pink) of the gene are important, and easily accessible from the browser view. GBrowse is also equipped with an extensive functionality and toolbox – further information can be found through the GMOD wiki (see “Relevant Website section”), including tutorials on more specialised features of GBrowse.

Discussion and Future Directions

With the wealth of databases and browsers available today for genomic research, researchers are in some ways spoilt for choice. However, as new pursuits such as personalised medicine progress, databases and browsers will need to be developed or adapted to meet these new demands. In a field with such fast-paced progress as genomics, not all future issues will be able to be predicted, and many will have to be dealt with as they arise. However, a few key directions are evident. The continued development of

high-throughput sequencing technology will likely continue to bring sequencing time and money costs down, increasing the availability of genomic data. Therefore, current databases will need to be optimised and adapted, and new databases created, to allow for such an influx of data. The curation and annotation of genomic data is already an issue, significant efforts put into generating the data, but less plentiful efforts put into assigning it with accurate annotations before adding it to databases; as data creation increases, this problem will only continue to get more and more relevant. More effective strategies around who is charged with curating and annotating the data in order to give it meaning, while keeping it reliable and reputable, need to be devised.

Closing Remarks

There are a multitude of databases and browsers available for genomic purposes, and with future increases in genomic data, there will only be more and more new databases formed, and new browsers created. No static article can keep up with the furious developments in the field; the hope is that this article can provide an introduction to the researcher looking into genomic databases and browsers for the first time, or looking for a refresher. This article is also not comprehensive, nor does it purport to be; with the already vast sea of resources available, no article could hope to offer a view of the whole current offering. If the reader requires more specialised databases and tools, hopefully the notions discussed herein provide a guide for what to look for.

Biographical Sketch

Dean Southwood is a PhD student in the Department of Molecular Sciences at Macquarie University. His background is in theoretical quantum physics, quantum computation, and bioinformatics. His current research interests involve genome analysis and improving basecalling algorithms using machine learning.

Shoba Ranganathan holds a Chair in Bioinformatics at Macquarie University since 2004. She has held research and academic positions in India, USA, Singapore and Australia as well as a consultancy in industry. Shoba's research addresses several key areas of bioinformatics to understand biological systems using computational approaches. Her group has achieved both experience and expertise in different aspects of computational biology, ranging from metabolites and small molecules to biochemical networks, pathway analysis and computational systems biology. She has authored as well as edited several books in as well as contributed several articles to Springer's Encyclopedia of Systems Biology. She is currently the Editor-in-Chief of Elsevier's Encyclopedia of Bioinformatics and Computational Biology as well as the Bioinformatics Section Editor for Elsevier's Reference Module in Life Sciences.

Comparative and Evolutionary Genomics

Introduction

Comparative genomics is a fundamental tool of genome analysis. Typically, DNA sequences from whole genomes and whole gene sets are compared to elucidate the common and different genomic features among two or more target organisms. Features common to two species are considered properties originating from the genome of their common ancestry, whereas different features reflect the distinct histories of each genome traced since the common ancestor. This rationale can be applied to any two species in a comparative analysis because all organisms on the Earth can be connected to a single phylogenetic tree (Fig. 1). Seen in this sense, comparative genomics is equivalent to evolutionary genomics.

However, caution is required in comparative analyses because exceptional events, such as horizontal gene transfer and convergent evolution, can often be detected at levels more than expected. In such cases, it is necessary to carefully confirm the accuracy of the data and the correctness of the analytical process. Whether the result can be verified by other independent methods should also be considered.

Previous reports on comparative genomics are rich examples of the types of analyses and modifications performed for each case. In this report, the achievements of comparative genome analysis are discussed in order to unravel the evolution of metazoans, and the analytical methods used in these studies and the knowledge obtained from application of these methods are outlined.

Aspects of Comparative Genomics: Structure, Type of Change, and Evolutionary Distances

When performing comparative genomic analyses, the following three biological aspects should be considered: genome structure, types of structural change, and evolutionary distance.

Genome Structure and Types of Change

For convenience in genome analyses, a genomic DNA sequence can be divided into genomic “parts”, such as protein-coding genes, noncoding genes, and intergenic regions that include repeat and interspersed sequences, and other functional regions represented by cis-/trans-regulatory elements.

Each of these parts undergoes changes throughout a generation through the combination of several evolutionary mechanisms. In the evolution of protein-coding genes, Koonin classified the major mechanisms into the following five types of change: (i) direct descendants with some nucleotide changes; (ii) gene duplication; (iii) gene deletion; (iv) gene gain by horizontal gene transfer;

Fig. 1 Conceptual Diagram of Relationship of Taxonomic Distances in Comparative Genomics. Genome data can be obtained for X, Y and Z, each of which is an extant organism. X and Y are closer to each other than to Z. X and Z have evolved since they diverged from the common ancestral organism CA. When comparing the three types of X, Y, Z, the commonly observed features may be the characteristics of CA.

and (v) fusion, fission, and other genetic restructuring, including loss or gain of new domains on the gene (Koonin, 2005). In addition to these, (vi) emergence of a de novo gene is also mentioned often.

“Emergence of a de novo gene (have been frequently occurred)” is a relatively new concept. In this mechanism, a protein-coding gene emerges from noncoding DNA with some mutations. There are many unresolved problems in gene evolution, including the contribution rate. The mechanism was mainly discovered from the comparative genome analysis of closely related fly species (Begun *et al.*, 2006). The fixation rate of a de novo gene is still unknown. However, it seems certain that de novo genes are constantly created from noncoding regions at a certain evolutionary rate (Zhao *et al.*, 2014).

The above six mechanisms (i) to (vi) were originally described for the evolution of protein-coding genes. However, the same classification may also be applied to the other genomic parts by replacing them more general concepts, such as: (i) direct descendants, (ii) duplication, (iii) deletion, (iv) gain by horizontal transfer, (v) changes in partial structure, and (vi) de novo emergence.

The proportion of each genomic part differs greatly among organisms (Lindblad-Toh *et al.*, 2005). This suggests that each evolutionary mechanism works independently on each genomic part, resulting in the creation of differences in the characteristics of various genomes as a basis for forming biodiversity from common ancestry (Simakov and Kawashima, 2017).

For example, the number of gene losses since the common mammalian ancestor has been estimated as about 1000 for humans and about 2000 for dogs, which is almost twice the rate (Demuth *et al.*, 2006). As other examples from an comparative analysis of interspersed sequences, the proportion of repetitive sequences in the genome of limpet (*Lottia gigantea*) is reported to be only around 21%, whereas those in the genomes of Hydra (*Hydra magnipapillata*) and humans are 57% and 43%, respectively (Simakov *et al.*, 2013; Chapman *et al.*, 2010). In addition, the evolutionary rate of the relative position of each part also differs in genome evolution. Preservation of the gene position on a chromosome is represented by the concepts of synteny and linkage, each of which forms a genomic feature. Many microsynteny derived from the common ancestry are detected between the genomes of amphiox and chickens, but are not detected between the genomes of amphiox and tunicates. This suggests that the evolutionary rate of the chromosomal structure has considerable differences among animals.

Although there are major differences in the genomic features of each organism, we can infer those features of the common ancestor. Table 1 shows an example of the estimation value of genomic features of the metazoan ancestor (Simakov and Kawashima, 2017).

In any case, the genome has evolved by changing all genomic parts based on the above six mechanisms, making up the genomic features of extant organisms.

Evolutionary Distances and Taxonomic Data Bias

Evolutionary distances for comparative analysis

Evolutionary distances between the target species of comparative analysis are largely related to choosing an appropriate data type and the method to be used.

By way of one of the most basic methods of comparative genomics, finding a common genetic set is relatively simple in most cases, for any pair of organisms (e.g., even for human and bacteria, in The *C. elegans* Sequencing Consortium, 1998). In such analyses, it is necessary to correctly understand the concepts of “orthologs,” “paralogs,” and other related concepts. These concepts are detailed in the next Section “Homologous Genes: Orthologs, Paralogs, and Others”.

In contrast, biological discovery becomes difficult if the distance between the compared species is too far or too close in some cases. This can be easily understood by considering the sequence comparison of intergenic regions as an example. Generally, in comparing intergenic regions between two genetically distant species, few conserved sequences are found. On another front, comparison between very closely related or among the same species reveals nearly identical DNA sequences, such that almost no differences may be detected between two species unless a considerable number of sequences from multiple individuals are compared.

Conservation and differences among relative positions of genes on the DNA between two species provides a history of chromosomal evolution, also called as “conserved-synteny” or “conserved linkage.” Although more than hundreds of orthologous genes are conserved between fungi and animals (Li *et al.*, 2003), almost no conservation is found in most of the gene-order between these

Table 1 An example of the estimation value of genomic features of the metazoan ancestor

Genomic feature	Inferred ancestral values
Presumptive genome size	~300 Mb
Gene family number	7,000–8,000
Total gene number	>20,000
Average exon count	3–4
Repeat content	~30%
Macro-syntenic linkage groups	~10–17
Micro-syntenic linkage groups	~400

Note: Reproduced from Simakov O., Kawashima, T., 2017. Independent evolution of genomic characters during major metazoan transitions. *Dev. Biol.* 427, 179–192.

two possibly because they are highly distant evolutionarily. Only exceptional example is reported in which the order of three genes, *psmb 1*, *Tbp*, and *Pdcd 2*, is conserved among yeast, humans, and some other animals (Trachtulec and Forejt, 2001).

As described above, it is necessary to carefully ensure appropriate evolutionary distance among subject data before initiating comparative studies.

Biased genomic data

The result of comparative genome analyses is susceptible to taxon sampling. Unfortunately, considerable taxonomic-bias is commonly found in any usable sequence data in practice. To perform a comparative analysis correctly, researchers need to be recognize the extent of bias in the genomic data which they used.

In metazoans for example, the genome sequences of chordate animals are overwhelmingly numerous by total published data, followed by those of Arthropoda (the column of “Number of decoded species” in Fig. 2). In contrast, for other animal taxonomic groups at the phylum level, it is often observed that no genomic data have been decoded or only one or two species have decoded genomes (e.g., gray vertical bar A and B in Fig. 2). Of the genome data for the phylum Chordata, most of the data are overly concentrated in sub-phylum Vertebrata compared to the other two subphyla, Urochordata and Cephalochordata.

The main reason for the sequence data bias towards vertebrates is presumably because human-related research accounts for a major portion of biological studies. Especially from a medical perspective, the amount of sequence data for humans and their closely related species tends to be increased. Genome analysis of domestic animals is also actively pursued as it is probably considered valuable from an agricultural point of view, regardless mammals have a larger genome size being more than 1 Gb (Anderson and Georges, 2004). 16 metazoan species are known as major domestic animals including 15 of mammals (dog, goats, sheep, cattle, pig, horse, cat, camel, ferret, chicken, turkey, rabbit, guinea pig, llama, and alpaca) and an insect, silkworm (Morey, 1994; Banno et al., 2010). Of the 16 major domestic animals, genomes of 12 mammals and one insect have been decoded

Fig. 2 History of animal genomics. On the left side of the figure, 32 phyla of animals (metazoa) are described. There are various opinions as to how many are appropriate number for phylum level classification. Recently it classified often as fewer than 32 phylum. In the recent phylogenetic interpretation, all animal phyla are divided into two large groups, non-bilateria and bilateria. And the latter is classified further into three groups, Ecdysozoa, Lophotrochozoa and Deuterostomia. In the column of “the number of decoded species”, how many species of its genome was decoded from each animal phylum was described based on the data of NCBI Taxonomy Database at the end of 2017. On the left side of the figure, among the respective animal phyla, the animal species whole genome was first decoded are shown in chronological form. Looking at the gray bar (A and B), we can see that there are considerable bias in the number of genomes decoded for each animal phylum.

(Kirkness *et al.*, 2003; Lindblad-Toh *et al.*, 2005; Dong *et al.*, 2013; Jiang *et al.*, 2014; The Bovine Genome Sequencing and Analysis Consortium *et al.*, 2009; Rubin *et al.*, 2012; Wade *et al.*, 2009; Pontius *et al.*, 2007; The Bactrian Camels Genome Sequencing and Analysis Consortium, 2012; Peng *et al.*, 2014; Rubin *et al.*, 2010; Dalloul *et al.*, 2010; Carneiro *et al.*, 2014; Mita *et al.*, 2004; Xia *et al.*, 2004). For the remaining three other animals (guinea pig, llama, and alpaca), genome sequencing projects are still ongoing.

In several cases for the genome projects of the domestic animals, multiple strains and individuals have been re-sequenced for applying various methods of population genetics to identify the genes responsible for genetic features of domestic animals that have been acquired through the history of domestication. Some examples of such genome projects of domestic animals will be described later.

Early studies decoded the insect genome presumably because it includes the fruit-fly, which is a major model organism of basic experimental biology, and also because many of them have relatively small genome sizes (Adams *et al.*, 2000; Gregory, 2011). Another reason is that several insects are deeply involved in the human society; some of them are useful, such as bees and silkworms whereas others are pests including aphids and flour beetles (Grimmelikhuijzen *et al.*, 2007).

Thus, analysis of genome sequence data cannot avoid bias for various reasons and it may simply be correlated with the researcher's population in most cases. Thus, it is important to determine the existence of bias in published data when performing comparative genome analysis.

Comparison of Homologous Genes

Homologous Genes: Orthologs, Paralogs, and Others

During comparative analysis of genes, it is necessary to understand the types of homologous genes (Fig. 3). "Homologous genes" are defined as genes with a common evolutionary ancestry (Brown, 2007). "Homologous genes" are sometimes called homologs (or homologues), but homolog(ue) is originally a histological term introduced by Owen, and defined as "the same organ in different animals under every variety of form and function (Owen, 1843)". Thus, this term is often inappropriate for use in genomics. Instead "orthologs" and "paralogs" are used frequently, both of which are simply basic concepts for genes that have a common ancestor with respect to molecular evolution (Fig. 3(A)). Orthologs are determined as homologous genes that diverged as a result of a speciation event. Paralogs are defined as homologous genes that diverged as a result of a gene duplication event. Another related term that is not used frequently, is "xenologs," defined as "homologous genes that diverged as a result of lateral gene transfer" (Kristensen *et al.*, 2011).

"Outparalogs (Alloparalogs)," "Inparalogs (Symparalogs)," and "Co-orthologs" are also defined as terms for further fine classification (Sonnhammer and Koonin, 2002). Outparalogs are defined as paralogs that were duplicated before the speciation event. Inparalogs are defined as paralogs that were duplicated after the speciation event. If lineage-specific gene-duplications (or expansion) has occurred in one or both of a pair of orthologs after speciation, sister genes of such duplicated orthologs constitute one-to-many or many-to-many relationships, respectively. Such gene relationships are called co-orthologs. Co-orthologs are thus defined as paralogs produced by duplication of orthologs after a given speciation event.

Fig. 3 Homolog Related Concepts. Illustrated various homolog related concepts shown in the main text.

Homology Search and Functional Prediction

One of the main purposes of searching homologous genes is prediction of gene function. This is based on the knowledge that homologous genes often have similar functions (Toh *et al.*, 1983). Since orthologs and paralogs are descendants of a common ancestral gene, it is estimated that both their functions and sequences are likely to be preserved. For this reason, determining orthologs and paralogs is the most basic step in prediction of gene function in bioinformatics (Cabaldón and Koonin, 2013).

Since the number of genes for which function has been elucidated experimentally is overwhelmingly smaller than the number of sequenced genes, it is frequently noted that gene prediction based on homology search may have problems with accuracy (Benner, 1999). Meaningless annotations like “similar to a gene of unknown function,” are also accumulated in genome databases, and these are likely to be reused in other databases. Despite this, the search for homologous genes has not lost its significance as the first step in annotation of genes (Joshi and Xu, 2007).

Various methods are still being developed for ortholog determination in comparative genomics because it is difficult to accurately decide true homologous genes pairs for the entire gene set between two species. Therefore, in practice, “bidirectional best-hits” (BBH, also called “mutual best-hits” or “reciprocal best-hits”) from all gene-sets are treated as conventional candidates of homologous genes (Tatusov *et al.*, 1997; Kristensen *et al.*, 2011). Although BBH are commonly used, a little study has been performed to ascertain their reliability. BBH are considered to be appropriate for use in prokaryotes (Wolf and Koonin, 2012). In contrast, a marked increase in mistakes is reported when BBH are used for comparisons among metazoans or plants, probably because these have many duplicated genes (Dalquen and Dessimoz, 2013). Ortholog determination in the comparison of whole gene sets is thus a product of some compromise. The fact that various ortholog-databases continue to be generated based on various criteria also implies the difficulty of ortholog determination (Dessimoz *et al.*, 2012).

Besides predicting gene function, as will be described later, determination of homologous genes is required to find conserved-synteny and linkage in the entire genome to reconstruct chromosomal evolution.

Whole Genome Duplication

Whole genome duplication (WGD) is an evolutionary event in which the whole gene set of an organism has been duplicated, probably by chromosomal polyploidy and its fixation. WGD is postulated as one of the major sources of evolutionary innovations.

Although polyploidy is a common phenomenon in eukaryotes, evolutionary fixed WGDs are exceedingly rare. In metazoa, known WGD events are almost limited to vertebrate lineages includes famous two round WGD (2R) which is occurred on the common ancestor of vertebrates (Ohno, 1970; Van de Peer *et al.*, 2009, 2010). In invertebrates, it is also suggested that some lineages have experienced WGD although those traces are not so clearly like vertebrates (Yoshida *et al.*, 2011; Kenny *et al.*, 2016). In plants and fungi, WGD occurs relatively more frequently than in animals (Van de Peer *et al.*, 2009) but there is still some bias.

Each type of duplicated genes created by WGD has named based on their forming mechanisms, respectively (Fig. 3(B)). Gene pairs produced by WGD are a special subset of paralogs (Wolfe, 2000). Because of their evolutionary significance as described above, they are sometimes distinguished by terms such as “ohnologs,” or its synonym “syntenic paralogs” (Wolfe, 2004; Schnable *et al.*, 2012). A similar word is “homoeologs” (or “homeologs” as another spelling) defined as homologous genes resulting from allopolyploidy (Glover *et al.*, 2016). The term “ohnolog” is derived from the name of Susumu Ohno who first proposed the hypothesis that gene duplication plays a key role in evolution (Ohno, 1970; Wolfe, 2000). Allopolyploid is a polyploid individual which composed of a chromosome set composed of two (or more) chromosome set. It formed from the hybridization of two (or more) separate but closely related species. The difference between the definitions of ohnolog and homoeolog is that the former refers to paralog made by autopolyploidy and the latter refers to paralog made by allopolyploidy. However, if polyploidization arose very long ago, it can not distinguish which mechanism truly occurred for creating the paralogous gene-sets. In such cases where autopolyploidy or allopolyploidy can not be distinguished, the term “paleolog” is sometimes used conveniently. Another similar term is “syntelogs” representing orthologous genes shared across species (or isolates for viruses) with a common syntenic genome location (Hatcher *et al.*, 2014).

The evolutionary process of WGD is one of the key themes in evolutionary genomics. In general, duplicated genes tend to be fixed only when those are to take on different functions but otherwise to be lost immediately after the duplication event. However, WGD is an event that a large number of duplication has occurred at once, it was quite difficult to investigate the process of gene losses until the era of genomics.

Because the function of an ohnolog pairs is presumably redundant each other just after WGD, it is theoretically expected that one of the duplicated genes to be lost gradually. Interestingly, the rate of gene losses may differ depending on the types of genes. For example in metazoa, it is known that ohnolog genes which relevant to embryonic development tend to be conserved as paralog gene-set (Holland *et al.*, 1994).

To distinguish a true pair of ohnolog or homoeolog from other common paralogs is technically difficult. Various methods have been devised to extract the set of ohnolog that were thought to be made by WGD. Several models have been proposed why the conservation rate of developmental genes after WGD is high (for example, Holland *et al.*, 1994). A future explanation will be awaited as to why the same trend is shown for cell cycle regulators.

To extract the ohnolog created by 2R in vertebrate evolution, Dehal and Boore utilized a genome of an invertebrate which is branched before the 2R. Using a graph-based method for this purpose, they have developed a way to extract homologous genes of

which number encoded in the genome of invertebrates and vertebrates at a ratio of approximately 1:2 to 1:4, respectively (Dehal and Boore, 2005).

Nishida and his colleagues developed a method to determine ohnolog gene-pair and examined the rate of gene loss after the WGD which occurred the common ancestor of teleost fish (teleost genome duplication: TGD) (Inoue *et al.*, 2015). As a result of the analysis for the obtained ohnolog gene set, they found that the rate of loss of ohnolog is roughly approximated by a double-exponential curve (2-phase model). According to their “2 phase model” of gene loss after TGD, duplicated genes are rapidly lost immediately after the WGD event, and then slowly lose at a roughly constant rate.

It is estimated that the rapid rate of gene loss in the first phase probably depends on the deletion of contiguous clusters of genes or large chromosomal segments (“block loss”), but the details have not been clarified yet.

It may be even more difficult to accurately identify the set of paralogs in an allopolyploid (homoeolog). The african clawed frog *Xenopus laevis* is proposed to be an allotetraploid animal that arose via the interspecific hybridization of diploid progenitors followed by subsequent genome doubling. In the sequence-decoding and reconstruction of the whole-genome of this frog, researchers noticed that the possibility that the subgenome derived from the two progenitor frogs each retained unique transposable elements in their genome and that those elements had been fossilized in each genome (Session *et al.*, 2016). They have actually found three of such transposable element and succeeded in separating reconstructed DNA sequences into two homoeologous subgenomes using those fossilized transposable elements as markers.

Homoeologs in the *X. laevis* were extracted from those separated subgenomes thus obtained and the tendency of the gene-loss after WGD was investigated. Interestingly, it was found that not only the developmental genes but also cell cycle regulators are tend to be conserved as paralogs after WGD.

Comparative Domain Structure of Genes

Many proteins retain several functional domains in their amino acid sequences. Particularly in the evolution of eukaryotic protein coding regions, the complexity of the domain structure may have played a significant role in gene evolution (Patthy, 1999; Chothia *et al.*, 2003). As mentioned in Section “Genome Structure and Types of Change”, the evolution of the domain architecture of a gene is a known mechanism for the changes in the partial structures of genes. The presence of genes with a lineage-specific or clade-specific domain structure makes it difficult to find true orthologous relationships (Uchiyama, 2006).

In eukaryotes, because genes are divided into several segmented structures of exons, duplication, shuffling, or deletion of functional domains can occur relatively easily by DNA recombination, potentially producing genes with a novel domain structure.

Choanoflagellates are unicellular eukaryotes and the closest known relatives of animals. King *et al.* (2008) decoded the genome of a choanoflagellate, *Monosiga brevicollis*, and compared the protein structure against those of metazoans. They found that choanoflagellates and metazoans shared many domains in their genomes, but the multidomain structure in their genes differed. These findings suggested that abundant domain shuffling followed the separation of the choanoflagellate and metazoan lineages. Such shuffling may have created animal-specific proteins during evolution.

Acquisition of a new domain structure may also be involved in the evolution of metazoan traits. In vertebrates, the domain structure of aggrecan protein, a major component of cartilage, was created by a domain-shuffling event that occurred in the common ancestry of vertebrates (Kawashima *et al.*, 2009).

Comparative Genomics of Intergenic Regions

Studies of intergenic regions have exploited comparative genomics methodologies. Such strategies are based on the known tendency that not only the coding-region but also other functional elements are likely to be well conserved in DNA among closely related species; thus, functional genomic regions can be predicted to some degree from sequence comparisons. Unlike the coding region, which can be predicted using transcriptome data, prediction of functional motifs in intergenic regions has been difficult. One of the established strategies is collating with known elements in databases such as TRANSFAC, JSPAR, and PAZAR. However, it is difficult to obtain strong candidates of the true element using this method alone because usually many false positives are detected. Additionally, this method is often not suitable for taxonomically separated species. Thus, comparative genome sequences provide a simple and widely applicable method for narrowing the candidates.

Nowadays, more direct and powerful methods for experimentally targeting such regions have been developed. Typical examples of these experimental methods include chromatin immunoprecipitation-seq (ChIP-seq), DNase-seq, formaldehyde-assisted isolation of regulatory elements-seq (FAIRE-seq), and assay for transposase-accessible chromatin-seq (ATAC-seq); of these, the former is a method for determining target positions on DNA of particular DNA-binding proteins, and the latter three are methods for detecting the open-chromatin regions on DNA. However, comparative sequences are still useful for surveying functional elements through intergenic regions because they can be combined with a variety of other methods.

Boffelli reviewed some examples of early studies of surveying functional elements in intergenic regions by comparative genomics among vertebrates (Boffelli *et al.*, 2004). Two representative researches introduced in the review are referred here. Nobrega and Rubin compared the 2.6-Mb region of the human genome with the homologous region of the mouse, frog, and puffer fish genomes and found 20 short conserved sequences in the vicinity of the *DACH* gene (Nobrega *et al.*, 2003). At least six of

the sequences have been confirmed to function as enhancers in mouse embryos. As another example, Lettice and colleagues compared the sequences in the neighboring area of *SHH* genes among humans, chickens, and puffer fish and found a sequence preserved in the introns of another gene separated by 1 Mb or more. The sequence was experimentally confirmed as a strong candidate enhancer of the *SHH* gene (Lattice *et al.*, 2003).

Some tools (e.g., VISTA and PipMaker) can be used to detect the conserved element in noncoding regions by comparative sequences (Mayor *et al.*, 2000; Schwartz *et al.*, 2000). Using these tools, comparative analyses of intergenic regions has become easy for two or more organisms if the taxonomic distances are selected appropriately. However, if the distance between two species is far, detecting functional motifs is still difficult. Future studies in comparative genomics are needed to overcome this unsolved problem.

Comparison of Gene Order

Linkage and Synteny

During evolution, chromosomal rearrangements change the gene order little by little as generations recapitulate due to deletions, insertions, duplications, inversions, and translocations of some chromosomal parts. Nevertheless, the signatures of the gene order in the genome of the common ancestor have been preserved for a long period in their offspring. Such traces of gene order are called “synteny”, which is defined as the presence at least two pairs of homologous genes on a particular limited genomic region or the same chromosome, regardless of order (Nadeau and Sankoff, 1998; Trachtulec and Forejt, 2001). Another similar concept is conserved linkage, which is defined as the synteny of two or more pairs of orthologous genes in the same order and orientation. However, the nomenclature for the evolutionarily conserved gene order is not unified. Although the original definition is as described above, it is often confusing (Passarge *et al.*, 1999). Therefore, researchers should consider the intentions of authors when consulting the literature. Some reports have referred to synteny as the conservation of blocks of gene orders within two sets of chromosomes or DNA fragments (scaffolds) that are being compared with each other. Since draft genome analysis has become popular, comparative genomic analysis of fragmental DNAs with only several kb or Mb can be easily performed. In such analyses, analysts cannot find the conservation of genes at the chromosomal level, but can find groups of orthologs in the relatively short fragmented DNAs of two organisms. Such synteny is sometimes called conserved synteny-block.

Long-Term Conservation of Synteny

Particularly in eukaryotes, synteny and linkage are often conserved for a surprisingly extended period. For example, many synteny blocks have been found in humans and mice, although the two species diverged from a common ancestor about 75 million years ago. The synteny blocks between these two species are approximately 65 Mb in length. The total length of these synteny blocks has been reported to cover over 90% of the entire genome of humans and mice.

Synteny is found even among the more evolutionarily distant species of eukaryotes, in contrast to bacteria, in which traces of gene orders disappeared almost immediately in some cases (Koonin *et al.*, 2000). However, as the evolutionary distance increased, the conservation degree of gene order, i.e., both the number and size of detectable blocks, tends to decrease gradually. When analyzing such slight traces of synteny, we can distinguish between two types of conserved gene orders that span different genomic scales, i.e., microsynteny and macrosynteny (Putnam *et al.*, 2007). Microsynteny is a local genomic region in which a very limited number of gene orders are conserved. Compared with microsynteny, macrosynteny describes much larger ranges, those on the scale of (partial) chromosomes and including several (or sometimes hundreds of) genes.

In a comparison of two markedly distant species, it is necessary to determine whether synteny and linkage found in modern organisms are indeed derived from the gene order in the common ancestor. If traces of synteny are very faint, we should focus on short stretches of conserved gene orders (microsynteny), composed of only two or three genes with some inserted genes, in order to consider the possibility of false positives due to coincidence. By validating the conservation in more than three species, false positives for surveying synteny blocks under such soft filtering can be eliminated.

In the following, three examples of micro- and macrosynteny are shown. In all cases, the human genome was compared with the genome of another organism. The first was a comparison of humans with lancelets, the invertebrate that is closest to vertebrates; the second was a comparison of humans with sea anemones, the non-bilateral animal closest to bilateral animals; and the third was a comparison of humans and fungi.

Lancelets, or amphioxii, belong to the subphylum cephalochordata and are classified as the phylum chordata together with the subphyla Tunicata and Vertebrata. Molecular phylogenetic analysis has revealed that cephalochordata were the first branched organisms among these three about 550 million years ago. Putnam and colleagues reported that more than 1000 microsynteny blocks were found between lancelets and humans under conditions allowing up to 20 genes to intervene between consecutive pairs of orthologs on the respective genomes. Although this may include some false positives, the fact that the number was over six times the discovery rate compared with the randomly reordered control strongly suggested that most of the gene orders were conserved since the common ancestor (Putnam *et al.*, 2008).

It is unclear why microsynteny blocks are preserved for so long-period. In an attempt to explain this problem, Irimia *et al.* (2011) found that genes encoding transcription factors were more likely to preserve the order with neighboring genes than other types of genes.

Based on this trend, they proposed a model in which regulatory elements of the intergenic region moved into the intron of the adjacent gene and in which the order of two genes was often fixed under the evolutionary timescale.

Domestication and Comparative Animals

Domestic Organisms are Invaluable Resources In Comparative Genomics

Domestic animals and agricultural plants are good research subjects for comparative genomic analysis between closely related species (Andersson and Georges, 2004). These strains have well-known traits that have been chosen over the years, and multiple DNA samples of closely related strains are available. To utilize the advantages of domestic animals, we typically attempt two types of analyses for comparing genomes to elucidate the domestication process of target organisms. In the first approach, the main subject is the elucidation of the origin of domestication and the history of subsequent propagation. In contrast, in the second approach, the aim is to find genes associated with traits relevant to domestication. In both of the approaches, data for sequence variations (primarily single nucleotide polymorphisms [SNPs]) are collected from several strains.

Origin and History of Domestication

Molecular phylogenetic analyses are used for the first approach to elucidate the domestication process. For this purpose, in addition to the genomes of multiple domestic strains, the genomes of the wild species closest to those domesticated strains are decoded, as are genomes of as many extant domestic strains as possible. When creating a species tree from amino acid or RNA sequences, using a long sequence created by concatenating a set of orthologs, rather than using only one gene, is the most common method (Delsuc *et al.*, 2005). For comparing closely related species, such as domestic organisms of different lines, SNP data gathered from comparative whole genomes are also useful for constructing a species tree (Guo *et al.*, 2013). In order to correct information on branching times, it is useful to calibrate the molecular phylogenetic tree based on paleontological data, such as fossil records and geological information. Some projects have succeeded in decoding even the DNA sequence from the fossils of ancestral animals to trace the process of domestication. In cases in which the fossil DNA of ancestral-related organisms can be obtained, it is possible to deduce the evolutionary rate up to the branching time with the extant taxa.

As an example of research on horse domestication, one research group succeeded in sequencing a draft genome from a horse bone recovered from permafrost dated to approximately 560–780 thousand years ago (Orland *et al.*, 2013). The group compared the obtained genome with the genomes of several modern horses and concluded that the common ancestor of all contemporary horses, zebras, and donkeys originated 4.0–4.5 million years ago.

Dogs are the first domesticated animal for which the genome was decoded. In the dog genome, many genes are missing compared with other mammals. Indeed, approximately 2000 genes may have been substantially mutated or lost from the dog genome after branching of dogs from the common ancestor of other mammals (Kirkness *et al.*, 2003; The Bovine Genome Sequencing and Analysis Consortium *et al.*, 2009). However, in the decoding of other domesticated animals, e.g., cows and pigs, such substantial gene losses have not been observed. Although it is difficult to determine the specific number of genes, and no reports have clearly described the number of genes lost during dog evolution, the results of comparative gene numbers among mammals in some papers are all similar; all results show that approximately 2000 genes have been lost in dogs. These findings related to gene losses may involve the evolution of dogs with various unique morphologies; further studies are needed to clarify these findings.

Notably, dogs were the first domesticated animals, separated from a group of wolves living with humans. The first branching time was estimated to be about 14,000 years ago, after which, two major changes occurred. A wide range of multiplications have also been made, particularly in the last 200 years.

Genome-Wide Association Study (GWAS) and Selective Sweep

The second approach is called GWAS, which uses sequence variations in the whole genome together with the phenotype and pedigree information to perform association analysis and to identify the loci of genes or regulatory elements that are important for the traits of interest (Zhang *et al.*, 2012). Each domestic animal has evolved specific traits, such as meat, egg, or fur productivity. Those traits are expected to be acquired by strong selection pressures. Therefore, by comparing the genomes among strains, the loci dominantly selected in each strain can be identified.

When analyzing the distribution of SNPs from a GWAS, “selective sweep” is frequently noted (Boffelli *et al.*, 2004). Selective sweep refers to a process by which a new advantageous mutation eliminates or reduces variation in linked neutral sites as it increases in frequency in the population (Nielsen *et al.*, 2005). This phenomenon is also called “genetic hitchhiking”. Since specific traits of domestic animals work predominantly by artificial selection, selective sweeps are expected to be observed in the neighboring region of the causative gene(s) of the trait. For example, according to the report of the first whole genome SNP analysis in cattle, the *MSTN* gene, which is related to muscle formation, was present in one of the regions where a strong signal of a selective sweep was detected in the genome of two beef cattle strains (The Bovine HapMap Consortium, 2009).

Another similar example is the genomic analyses of chickens. In chicken genomics, SNPs have been collected from eight different populations of domestic chickens, including broiler (meat-producing) and layer (egg-producing) lines as well as a red jungle fowl, the major wild ancestor. A selective sweep at the locus for thyroid-stimulating hormone receptor (TSHR) was performed for all domestic chickens. The *TSHR* gene is known to be involved in the regulation of photoperiod control of reproduction in birds and mammals. The authors demonstrated that mutations in this gene and its neighboring region were related to early domestication of chickens, as shown by the absence of strict regulation of seasonal reproduction in natural populations.

Future Directions

In the 2000s, whole genome analysis became possible in both prokaryotes and eukaryotes, and a comparative genome analysis was undertaken. Initially, there was a focus on the presence or absence of orthologs as well as the detection of conserved intergenic regions in major comparative genomics. Subsequently, the performance of the high-throughput DNA sequencing has improved, and it is now feasible to compare the genome sequences of multiple individuals for the same species or closely related strains. For this reason, the theories advocated in classical population genetics are now being actively tested with various actual data. This trend is expected to continue.

With the development of several “finishing” technologies, many projects aiming to reconstruct genomic sequences that had been stopped at the “draft” level may be able to be completed to the number of chromosomal arms in the near future (Eisenstein, 2015). If more genomes are completely sequenced, researchers in the field of evolutionary genomics will be able to elucidate the history of structural changes in the chromosome, such as chromosomal rearrangement or segmental duplication.

Closing Remarks

Both the terms “comparative genomics” and “evolutionary genomics” tend to be used when referring to a wide range of fields. In this report, the following definition was applied: “comparison of all gene sets in two or more species of organisms”. However, this definition has expanded to include comparisons of intergenic regions, SNPs, and chromosomal structures. Examples in this report focuses on comparative and evolutionary genomics of eukaryotes. Because comparative genomic analysis of bacteria also differs greatly from that of eukaryotes, it has not been described in this paper. Additionally, the examples provided herein are biased toward the study of animals; however, it is expected that the information presented in this report will still be helpful because the basic trends of the described studies were not different from those in fungi and plants. Notably, the genomic structure of unicellular eukaryotes has not yet been elucidated. It is possible that the basic structures of genomes in these organisms may deviate considerably from those of previously decoded genomes. Accordingly, further genome decoding and comparative analyses are needed.

Acknowledgements

I thank Yi-jun Luo, Oleg Simakov, Jun Inoue, and Hirokazu Chiba who kindly commented on the very early version of this document. I'm grateful to anonymous reviewer K.K. who reads the final manuscript intensively and gave useful comments. I greatly appreciate that Masanori Arita, Naoko Murakata and Takako Ohnuki supported the office procedure related to writing work. Part of this work was supported by the Kaken-hi Grant (no.: 17K19248).

Genome Alignment

Tetsushi Yada, Kyushu Institute of Technology, Fukuoka, Japan

© 2019 Elsevier Inc. All rights reserved.

Introduction

Genome alignment is the alignment of genome sequences; it can be considered as a way to reformat a genome sequence dataset in order to facilitate the comparison of evolutionarily related genomes. We can also consider a genome alignment as a prediction of homology (i.e., shared origin, see the next section) at the nucleotide level between two or more genomes (Dewey and Pachter, 2006; Dewey, 2012).

Regarding the question of why we (re)construct genome alignments, the following sentence would neatly summarize its answers that have been given thus far (e.g., Dubchak and Pachter, 2002; Frazer *et al.*, 2003; Brudno and Dubchak, 2005; Dewey and Pachter, 2006; Margulies and Birney, 2008; Dewey, 2012; Thompson, 2016a; Bleidorn, 2017): “we (re)construct genome alignments *in order to exploit the evolutionary information inscribed in the genome sequences.*” (Note: This sentence itself is our homage to Dr. Hitoshi Kihara, a renowned plant geneticist who once wrote: “The history of the earth is recorded in the layers of its crust; the history of all organisms is *inscribed* in the chromosomes” (originally in Japanese) (Kihara, 1947)).

Here, let us elaborate on this sentence. The genome sequences of all extant living organisms are, after all, the products of billions of years of evolution, starting from the genome(s) of the most recent common ancestor(s) of life.

During the course of evolution, the genome sequences have gradually (or suddenly) changed, and have accumulated mutations such as base substitutions, insertions, deletions (e.g., Graur and Li, 2000), and large-scale rearrangements such as inversions, translocations, duplications, etc. (e.g., Lupski, 2007; Lynch, 2007; Gu *et al.*, 2008; Lee *et al.*, 2017). In other words, information on the evolution is ‘inscribed’ in the genome sequences in the form of accumulated mutations. Broadly speaking, the amount of difference between two genome sequences should be bigger as they diverge earlier. Therefore, by comparing the genome sequences of two species (or individuals) and quantifying the differences, we can estimate the *evolutionary distance* between them, that is, how closely (or distantly) the two species (or individuals) are related to each other (e.g., Waterston *et al.*, 2002; Gibbs *et al.*, 2004). If we extend the comparison to that of three or more genomes, we can infer the phylogenetic relationships among them, that is, the order in which each genome (or lineage) diverged from others (e.g., Clark *et al.*, 2007; Sheng *et al.*, 2011; Sahl *et al.*, 2012; Prabha *et al.*, 2014). Moreover, by meticulously examining the patterns of differences between the genomes, we can identify what types of mutations (like substitutions, insertions, deletions, inversions, translocations and duplications) occurred, and how and when (or where in the phylogenetic tree of the genomes) they occurred (e.g., Kent *et al.*, 2003; Watanabe *et al.*, 2004; Ma *et al.*, 2006; Clark *et al.*, 2007; Wang *et al.*, 2015). Thus, genome alignments provide integral materials for the study of molecular evolution and phylogenetics (e.g., Gascuel, 2005; Saitou, 2013).

But this is not all; genome alignments also enable us to identify functionally important regions of the genomes. According to the neutral theory of molecular evolution (Kimura, 1968, 1983), non-functional parts of a genome by default evolve neutrally, i.e., without any selective pressure, and mutations on them are occasionally fixed in the population due to genetic drift. On the other hand, if the parts have some biologically important functions, mutations on them are likely to disrupt the functions and thus less likely to be fixed than neutrally (Kimura and Ohta, 1974). Therefore, the alignment of genomes that are appropriately evolutionarily far apart will highlight potentially functional parts of the genomic sequences as those showing significantly less frequent changes than the neutral background (e.g., Kellis *et al.*, 2003; Birney *et al.*, 2007; Stark *et al.*, 2007; Tseng and Tompa, 2009; Hupalo and Kern, 2013). In contrast, if the parts show significantly more frequent changes than the neutral background, the parts may have been under (continuous) positive selection pressure, maybe because they are involved in the responses to incessantly changing environments, including interactions between hosts and pathogens or parasites and between males and females (e.g., Hughes and Nei, 1988; Swanson and Vacquier, 2002; Sackton *et al.*, 2007; Wong, 2011).

For that matter, the conservation of synteny (i.e., colocalization within a single chromosome, see Section “Conserved Synteny and Collinearity”) of genomic elements (including genes) during a long evolutionary period may indicate either that their synteny itself is functionally significant and/or that the region in between the elements is also functionally essential (e.g., Ferrier and Holland, 2001; Hurst *et al.*, 2004; Kikuta *et al.*, 2007; Engström *et al.*, 2007; Dewey, 2012; Schnable, 2015; Bleidorn, 2017), because otherwise the synteny would eventually be disrupted by some genomic rearrangements. Also in this sense, genome alignments are useful because they enable us to reveal the regions of conserved synteny and possibly to infer the large-scale structures of ancestral genomes (e.g., Tesler, 2002; Kent *et al.*, 2003; Ma *et al.*, 2006, 2008).

Because of such multi-faceted utility, genome alignment has been a corner stone of comparative genomics, whose main purposes are to identify conserved (and thus functionally important) elements and regions in the genomes and to study underlying evolutionary mechanisms and forces operating on the genomes (e.g., Frazer *et al.*, 2003; Brudno and Dubchak, 2005; Margulies and Birney, 2008; Dewey, 2012).

During the past two decades, genome alignment has been a subject of intensive study and vigorous efforts, and numerous algorithms, methods, and programs have been published thus far. Therefore, it is virtually impossible to exhaust the past studies. Hence we will overview the past developments in this area of research while discussing a number of methods that particularly caught our attention. If the readers want more extensive, or nearly comprehensive, information on this subject, we recommend them to read not only this article but also some other reviews, such as (Dubchak and Pachter, 2002; Frazer *et al.*, 2003; Brudno and Dubchak, 2005; Jayaraj, 2006; Dewey and Pachter, 2006; Margulies and Birney, 2008) for early developments, and (Dewey, 2012;

Earl *et al.*, 2014; Kehr *et al.*, 2014; Thompson, 2016a) for relatively recent developments. Moreover, because of the space limitation, we will focus on the methods to align two or more long sequences (at least on the order of 100 kb), and will not discuss methods to align shorter sequences, such as the standard aligners for, e.g., protein-coding or RNA genes (reviewed, e.g., in Kumar and Filipinski, 2007; Notredame, 2007; Aniba *et al.*, 2010; Löytynoja, 2012; Iantorno *et al.*, 2014) or methods to map the reads from Next-Generation Sequencers to a reference genome (reviewed, e.g., in Cordero *et al.*, 2012; Lee and Tang, 2012; Bahassi and Stambrook, 2014; Mielczarek and Szyda, 2016; Smith and Yun, 2017). Those who are interested in these topics should refer to the reviews cited just above and/or the relevant articles in this Encyclopedia.

Background/Fundamentals

This section provides some basic information that is necessary for discussing genome alignment.

Homology

In molecular evolution (including evolutionary genomics), the term “homology” means the sharing of evolutionary origin between two genomic elements (or among three or more elements). That is, two genomic elements are “homologous” to each other if they are descended from a common ancestral element (e.g., Fitch, 1970, 2000). The concept of homology can be extended (or reduced) to the nucleotide level (Fitch, 2000; Dewey and Pachter, 2006; Dewey, 2012).

In the traditional matrix (row-column) format of a sequence alignment, each column consists of homologous nucleotides from the aligned sequences, and each row represents an aligned sequence interspersed with gaps that indicate the lack of the corresponding nucleotides. Usually, each nucleotide is represented by a one-letter abbreviation code of its base (‘A’ for adenine, ‘C’ for cytosine, ‘G’ for guanine, and ‘T’ for thymine), and each gap is represented by a hyphen (‘-’). Actually, this traditional matrix representation is not enough to represent a genome alignment, because it is not flexible enough to accommodate genome rearrangements (such as inversions) and duplications. Nevertheless, the matrix representation still remains a crucial building block of almost all formats of genome alignments.

In molecular evolution, the homology relationship can be broadly classified into three categories: “orthology”, “paralogy”, and “xenology” (Fitch, 1970, 2000; Gray and Fitch, 1983). The two homologous elements are “orthologous” if they diverged from the common ancestor as a result of speciation; they are “paralogous” if their divergence is due to duplication; they are “xenologous” if at least one horizontal transfer contributed to the evolutionary path between them.

When discussing different types of genome alignments, it is sometimes convenient to further sub-classify the categories of orthology and paralogy, because such sub-classes could help clarify particular goals of different methods. Especially, it is important to note that, in general, orthology is not necessarily a one-to-one correspondence, because a genome element may have duplicated after speciation. “Topoorthology” (or “positional orthology”) is a special subclass of orthology (Dewey and Pachter, 2006; Dewey, 2012); a pair of orthologous elements are topoorthologous if the evolutionary path between them does not go through any duplication event that changed the genomic position of the element. (Such duplication events include retrotranspositions and interspersed segmental duplications, but do not include tandem duplications.) In other words, a pair of topoorthologous elements have never changed their genomic positions due to duplications (though they may have changed positions via rearrangements,) since their divergence due to speciation. This notion of “topoorthology” may be closer to what some readers might have considered as “orthology”; because topoorthologous genes usually share the same ancestral genomic context, they are much more likely to conserve functions than non-topoorthologous orthologous genes are (Dewey, 2012).

Conserved Synteny and Collinearity

During the course of evolution, a genome has undergone rearrangements, thus some long-range organizations of the genomic sequence have been disrupted. When aligning whole genomes, we are supposed to align segments that have escaped (especially large-scale) rearrangements since the divergence of the genomes. Thus, some terms have been defined to represent such situations (e.g., Gregory *et al.*, 2002; Frazer *et al.*, 2003; Margulies and Birney, 2008). When two or more elements in a genome reside on the same chromosome, they are referred to as “syntenic”. When two or more elements reside on a single chromosome in one species and their orthologous counterparts also reside on a single chromosome in the other species, the situation is referred to as “conserved synteny”. It should be noted that conserved syntenic blocks (or regions) may have undergone small-scale rearrangements confined within them, thus the order among the elements may not be conserved. When the order is also conserved within the pair of conserved syntenic regions, Gregory *et al.* (2002) (and also Frazer *et al.*, 2003) referred to them as “conserved segments”. However, they did not mention the relative orientations of the elements, which may change via (small-scale) inversions. When both the order and the orientations are also conserved within a pair of conserved syntenic regions, we usually refer to the regions as having “conserved collinearity” or, for short, being “collinear” (to each other). (Conserved) collinearity implies that the regions have not undergone any rearrangements since their divergence. Considering these original definitions, the term “synteny mapping” should rigorously mean pairing up conserved syntenic blocks in two genomes (or its extension to more genomes), though the term has come to imply finding collinear regions (as pointed out by Margulies and Birney, 2008). Moreover, the notions of

conserved syntenic and collinearity can be extended to any homologous segments (including paralogous ones), not limited to orthologous ones. Thus, [Margulies and Birney \(2008\)](#) proposed to use the term “reconstructing homologous collinearity” instead of “syntenic mapping”. It should be noted, however, that some programs are *literally* syntenic mappers, because they do not care much about the order or orientations of the elements within each block. Therefore, we will refer to this kind of programs collectively as “syntenic mappers”, while keeping in mind that some of them are actually programs to reconstruct homologous collinearity. (When necessary, we will clearly distinguish whether a program reconstructs conserved syntenic or collinearity).

Local, Global, and “Glocal” Alignment

Traditionally, there have been two types of sequence alignment methods, local and global. Local alignment methods align only those regions of the sequences that are suspected to be homologous (based on their similarities). In contrast, global alignment methods “force” to align the sequences from the beginning to the end. Merits of local alignment are: (i) it could avoid false alignment of non-homologous regions, especially those neighbouring homologous regions; and (ii) it can even align regions that are no longer collinear as a result of rearrangements. Demerits of local alignment are: (i) it could miss weakly homologous regions located near highly homologous regions; and (ii) it could mistake by-chance similarities as homologies, even if they are isolated from other homologous regions. Pros and cons of global alignment are opposite from those of local alignment.

In 2003, an intermediate concept, “glocal alignment” was proposed ([Brudno et al., 2003c](#)). Glocal alignment is intended to be like local alignment in that it can align those regions that have undergone rearrangements and duplications (and, in addition, suggests the presence of these events), and like global alignment in that it can potentially detect weak homologies if they are neighbouring strongly homologous regions.

Originally, [Brudno et al. \(2003c\)](#) defined a (pairwise) glocal alignment as “a series of operations that transform one sequence into the other”. They considered that the operations include insertions, deletions, point mutations, inversions, translocations and duplications, and that the total edit distance between the two sequences is the sum of penalties incurred by individual operations.

Topic

Major Challenges on Genome Alignment

When aligning genome sequences, some major challenges need to be overcome (e.g., [Dubchak and Pachter, 2002](#); [Margulies and Birney, 2008](#); [Thompson, 2016a](#)); especially pressing among them are: (1) time (and space) requirement, and (2) rearrangements and duplications.

- (1) When optimising simple objective functions for pair-wise sequence alignment (PWA), dynamic programming (DP) algorithms have long been used, such as Needleman-Wunsch (NW) ([Needleman and Wunsch, 1970](#)) for global alignment, Smith-Waterman (SW) ([Smith and Waterman, 1981](#)) for local alignment, and their various improvements (e.g., [Hirschberg, 1975](#); [Gotoh, 1982](#); [Myers and Miller, 1988](#)). These algorithms have the time complexity quadratic in the sequence length and space complexity quadratic or linear in the sequence length. When aligning sequences such as protein-coding genes and RNA genes, which are not so long, they do their jobs in a reasonable amount of time. However, when aligning genome sequences, each of which consists of millions to billions of bases, these DP algorithms could consume an enormous amount of time, making such computation impractical.

One heuristic to avoid this problem is to first find short regions showing high similarity (commonly called “seeds”) via a fast heuristic method and to restrict the (2-dimensional) search space of DP to those around, and/or in between, the seeds. This could drastically reduce the computational time. There are two major approaches based on this “seeding” heuristics (e.g., [Dubchak and Pachter, 2002](#); [Jayaraj, 2006](#); [Dewey and Pachter, 2006](#); [Margulies and Birney, 2008](#); [Dewey, 2012](#); [Thompson, 2016a](#)): one is to extend each seed on both sides via some modified version of the SW algorithm (“seed-and-extend”), somewhat similarly to gapped BLAST ([Altschul et al., 1997](#)), and the other is to chain mutually consistent seeds first and then to use the chained seeds as “anchors” and to align the regions in between the neighbouring anchors (“seed-and-chain”, or “anchoring”). (For the chaining algorithms in early days, see, e.g., [Ohlebusch and Abouelhoda, 2005](#)). Usually, the regions in between the neighbouring anchors are globally aligned, but some aligners locally align the regions. (The “seed-and-extend” strategy usually produces a set of local alignments, which may sometimes be chained afterwards (e.g., [Kent et al., 2003](#))). When aligning three or more sequences, even if the sequences are not so long, it could take an enormous amount of time even for a DP to exhaustively search the alignment space (e.g., [Gusfield, 1997](#)); in fact, it has been shown that such a problem with some-of-pairs scoring is NP hard ([Wang and Jiang, 1994](#)). Thus, to reconstruct a multiple sequence alignment (MSA), we must resort to some heuristics (e.g., [Gusfield, 1997](#); [Notredame, 2007](#); [Kemena and Notredame, 2009](#); [Löytynoja, 2012](#)). Among the most popular heuristics is the progressive alignment ([Hogeweg and Hesper, 1984](#); [Feng and Doolittle, 1987](#)), which iteratively performs pairwise alignment of sequences or sub-alignments at each internal node of a guide tree, from leaves upwards, and finally constructs an MSA of all input sequences at the root. Multiple genome aligners that have been developed thus far mostly combine some heuristics for MSA with either “seed-and-extend” or “anchoring” heuristics.

- (2) Traditionally, sequence alignment algorithms have been built under simple models that only consider base substitutions, insertions, and deletions (e.g., [Gusfield, 1997](#); [Kumar and Filipinski, 2007](#); [Notredame, 2007](#); [Löytynoja, 2012](#)), thus they have only been able to produce collinear alignments, where the order and orientations of the homologous elements are conserved. However, it is undeniable that genome sequences have undergone other types of mutations such as rearrangements (inversions, translocations, etc.) and duplications (e.g., [Kent et al., 2003](#); [Pevzner and Tesler, 2003](#); [Ma et al., 2006](#); [Lupski, 2007](#); [Lynch, 2007](#); [Clark et al., 2007](#); [Lee et al., 2017](#)). Therefore, when aligning genome sequences, it becomes inevitable to handle these rearrangements and duplications, in addition to substitutions, insertions, and deletions that have been traditionally dealt with. Currently, a common strategy to address this challenge is splitting the genome alignment problem into two sub-problems (e.g., [Dewey and Pachter, 2006](#); [Margulies and Birney, 2008](#); [Dewey, 2012](#)): (1) finding the regions of conserved collinearity (or conserved synteny), and (2) aligning each collinear (or syntenic) region at the nucleotide level. In early days, these two subproblems were addressed by separate programs (or separate components of a pipeline) (e.g., [Couronne et al., 2003](#); [Brudno et al., 2004](#)), namely, a homologous collinearity reconstruction method (or a “synteny mapper”) and a collinear aligner. Around since two important concepts, “glocal alignment” ([Brudno et al., 2003c](#)) (see also Section “Local, Global, and “glocal” Alignment” above) and a “threaded blockset” ([Blanchette et al., 2004](#)), were proposed, however, many research groups have developed “non-collinear aligners”, each of which addresses the two subproblems in a single run (see also the “Approaches” Section below). Such programs may be advantageous, because they may potentially become able to refine the result of the first component taking account of the result of the second component (e.g., [Paten et al., 2011](#)). Nevertheless, the development of collinear genome aligners is still an area of active research, because they are important components of the non-collinear aligners.

[Blanchette et al. \(2004\)](#) defined the “threaded blockset” as a set of “blocks” that are “threaded” by each of the original input sequences. (Here, a “block” is a set of mutually homologous collinear segments from the original input sequences (or their reverse complements), and a sequence is said to “thread” the blockset if the blockset contains completely and non-redundantly the sequence as a whole. It should be noted that a block is permitted to consist only of a segment of a single sequence.) In our view, this threaded blockset could be regarded as a representation of a glocal alignment, if the threading information is explicitly presented. In fact, a threaded blockset is highly similar to a graph-based alignment (reviewed e.g. in [Kehr et al., 2014](#)), which could be considered as a sort of glocal alignment (as argued by [Darling et al., 2010](#)). And, indeed, the developers of a graph-based aligner (the A-Brujin alignment method) even stated that their aligner “is able to automatically generate threaded blockset for genomic sequence alignment” ([Raphael et al., 2004](#)).

A yet another similar, but distinct, class of non-collinear aligners is the positional homology genome alignment method ([Darling et al., 2004, 2010](#)), which may be traced back to MUMmer (version 2) ([Delcher et al., 2002](#)). Like glocal aligners, they can deal with rearrangements, such as inversions and translocations. Unlike glocal aligners, however, they will not attempt to align paralogous regions within the same genome, because their primary goal is to align positional orthologs (topoorthologs) of different genomes. This type of aligner will be useful if the focus of the downstream study is on identifying and analyzing topoorthologs, although it may not be suitable for detailed analyses of duplication-related phenomena ([Darling et al., 2010](#)).

Major Steps in Genome Alignment

As somewhat discussed above, alignment of genome sequences poses several challenges. Therefore, traditionally, genome alignments have been constructed in several steps. The major steps involved in pairwise alignment are: (1) reconstructing homologous collinearity (e.g., [Margulies and Birney, 2008](#)) (also known as “synteny mapping” (e.g., [Thompson, 2016a](#)) or “homology mapping” (e.g., [Dewey and Pachter, 2006](#); [Dewey, 2012](#))); then, for each collinear region, (2) finding “seeds” (i.e., short, highly similar pairs (or sets) of subsequences), (3) selecting promising seeds, (4) completing the alignments around the selected seeds (for seed-and-extend) or in between them (for anchoring); and (5) displaying and viewing the resulting genome alignment.

Many programs perform steps (2)–(3) or (2)–(4) recursively, and gradually narrows down the search space, aiming to enhance the sensitivity and/or accuracy of the resulting alignment, and/or computational speed. When a pipeline consists mainly of a synteny mapper and a collinear aligner, all the steps from (1) to (4) are usually performed separately. Many graph-based aligners also seem to follow this practice; in this case, step (1) is usually performed by a component of the program separate from the component dealing with steps (2)–(4). Some non-collinear aligners, however, functionally merges step (1) with steps (2)–(3). Furthermore, some seed-and-extend type local aligners perform steps (2)–(4) first and, when necessary, performs step (1) later, using the output of step (4).

As briefly mentioned above, multiple genome alignment involves a heuristic MSA step (such as progressive alignment) in addition to the aforementioned steps (1)–(4). (Note: Here, we consider step (5) as a separate, absolutely final step.) Therefore, another dimension of variety arises regarding when to perform the MSA-dedicated heuristics; it could be either before step (1), before step (2) or (3), before step (4), or after all steps, (1)–(4).

In early days, step (1) mostly focused on finding orthologous collinear (or syntenic) regions. However, some later methods can also find paralogous collinear (or syntenic) regions.

Step (2) can vary widely depending on the types of seeds and the types of data structure to store the seeds. Seeds can be un-spaced (i.e., consecutive) or spaced (i.e., containing some positions that will be ignored), and also can be exact matches or inexact matches, or even with some gaps. Particular types of spaced seed patterns were shown to enhance the sensitivity of the alignment as well as computational speed, because they substantially reduce the correlation between overlapping seeds

(Ma *et al.*, 2002); these seed patterns have been used by some aligners. Regarding the seed-storing data structure, suffix-trees (or suffix-arrays) and hash-tables seem to be most widely used. Suffix-trees are good at finding exact or nearly exact matches (e.g., Delcher *et al.*, 1999), whereas hash-tables can be used for finding considerably in-exact matches (e.g., Schwartz *et al.*, 2003). A notable seed-finding method is CHAOS, which can find even gapped matches and use them as seeds (Brudno *et al.*, 2003a); it is thus expected to work also on genomes that are somewhat distantly related to each other. More recently, a new type of seeds, “adaptive seeds”, have been proposed (Kielbasa *et al.*, 2011). An adaptive seed is a short match (of any length) that occurs in a target genome less frequently than a specified threshold. They are robust against regional heterogeneity of base composition and repetitive elements.

Step (3) is performed either by imposing some thresholds on each seed (mainly for seed-and-extend) and/or by chaining mutually consistent seeds (for “anchoring”).

Methods for step (4) could be classified in terms of the broad category (local, global, or probabilistic), the scoring scheme (a traditional score with match rewards, mismatch penalties and affine gap penalties, a consistency score (e.g., Paten *et al.* 2008a), an expected accuracy (e.g., Bradley *et al.* 2009), etc.), and so forth. Some methods even apply external collinear aligners (e.g., Thompson *et al.*, 1994; Edgar, 2004; Katoh and Toh, 2008) to this step.

Regarding step (5), there are some programs (viewers and browsers) dedicated particularly to displaying the alignment (e.g., Mayor *et al.*, 2000; Schwartz *et al.*, 2000; Frazer *et al.*, 2004; Elnitski *et al.*, 2010; Nguyen *et al.*, 2014; Poliakov *et al.*, 2014). But many aligners come with their own internal (or accompanying) viewers (e.g., Darling *et al.*, 2010). In addition, some web-sites, such as Ensembl (Herrero *et al.*, 2016), Galaxy (Afgan *et al.*, 2016), UCSC Genome Browser (Miller *et al.*, 2007; Tyner *et al.*, 2017), and VISTA browser (e.g., Poliakov *et al.*, 2014), store a number of genome alignments that are too large to be reconstructed by a single researcher (or laboratory), and their own dedicated browsers enable us to view the alignments in interactive and convenient manners, possibly with some annotations.

Approaches

To the best of our knowledge, the development of genome aligners started with MUMmer (Delcher *et al.*, 1999), a pairwise collinear local genome aligner employing “seed-and-chain” strategy based on a suffix-tree. (Note: MUMmer evolved into a non-collinear local aligner afterwards (Delcher *et al.*, 2002; Kurtz *et al.*, 2004)). After that, some (either local or collinear global) pairwise genome aligners were developed (e.g., Batzoglou *et al.*, 2000; Kent and Zahler, 2000; Ma *et al.*, 2002; Bray *et al.*, 2003; Schwartz *et al.*, 2003). Then, in 2002, “multiple genome aligner” (MGA), the first collinear multiple global genome aligner, was published (Höhl *et al.*, 2002), and some (either global or local) collinear multiple aligners followed (e.g., Brudno *et al.*, 2003a, b; Blanchette *et al.*, 2004; Bray and Pachter, 2004). (Note: Later, MLAGAN and TBA evolved into non-collinear multiple aligners; the former is glocal (Dubchak *et al.*, 2009), and the latter is local (discussed, e.g., in: Raphael *et al.*, 2004; Ovcharenko *et al.*, 2005; Margulies *et al.*, 2007)). It was in 2003 that the first (pairwise) non-collinear “glocal” genome aligner, Shuffle-LAGAN, was published (Brudno *et al.*, 2003c). And, in 2004, some non-collinear multiple genome aligners of different types were published (e.g., Darling *et al.*, 2004; Raphael *et al.*, 2004). Since then, non-collinear multiple aligners have been in the mainstream of genome aligner developments (e.g., Darling *et al.*, 2010; Angiuoli and Salzberg, 2011; Paten *et al.*, 2011), while pairwise aligners and collinear multiple aligners have also been vigorously developed with a variety of advanced features (e.g., Harris, 2007; Rausch *et al.*, 2008; Bradley *et al.*, 2009; Paten *et al.*, 2009; Kryukov and Saitou, 2010; Nakato and Gotoh, 2010; Kielbasa *et al.*, 2011).

Before non-collinear genome aligners became popularized, “synteny mappers” played a crucial role in whole-genome alignment pipelines (e.g., Couronne *et al.*, 2003; Kent *et al.*, 2003; Brudno *et al.*, 2004; Dewey and Pachter, 2006; Margulies and Birney, 2008; Paten *et al.*, 2008a). Even after the advent of non-collinear aligners, though, synteny mappers have been advanced steadily (Hachiya *et al.*, 2009; Pham and Pevzner, 2010; Drillon *et al.*, 2014; Tang *et al.*, 2015), maybe partly because gene-based analyses of synteny (and collinearity) remain handy and important (both by themselves and as preliminaries of functional and evolutionary analyses). Now, some state-of-the-art synteny mappers can handle quite a large number of genomes (e.g., Rödelberger and Dieterich, 2010; Proost *et al.*, 2012; Wang *et al.*, 2012; Minkin *et al.*, 2013).

In Supplementary Table S1, we have listed the approaches (such as methods, programs, and algorithms) discussed above and in the previous “Topic” section, as well as some additional ones that also caught our attention. In the table, the approaches are classified from several points of view, and each of them is also accompanied by some comments (on algorithms, scope, output formats, etc.) and notes, if at all. (The relevant references are listed in a separate sheet).

Supplementary data associated with this article can be found in the online version at <https://doi.org/10.1016/B978-0-12-809633-8.20237-9>.

Here are some caveats. It should be kept in mind that Supplementary Table S1 is far from exhaustive. Information that somewhat complements the table can be obtained, e.g., from the following sources: regarding aligners, the references cited in Introduction of this article; regarding synteny mappers, table 1 of Rödelberger and Dieterich (2010), supplementary table S1 of Proost *et al.* (2012), table 3 of Wang *et al.* (2012), table 1 of Tang *et al.* (2015), and a review (Ghiurcuta and Moret, 2014); regarding browsers and viewers, Introduction of Nguyen *et al.* (2014), and a review (Wang *et al.*, 2013).

As far as we know, among the numerous (stand-alone) synteny mappers that have been developed thus far, only Mercator, Enredo, Shuffle-LAGAN and its successor, SuperMap (Dubchak *et al.*, 2009), and some methods based on BLAT (Kent, 2002) (e.g., Brudno *et al.*, 2004) were combined with collinear aligners to produce multiple genome alignments. Other synteny mappers have

been used mainly for the evolutionary analyses of genome architectures (including whole-genome duplications, segmental duplications, and tandem arrays of repeats) or genomic contexts of genes (including orthology, regulatory elements and gene families). It may be worth exploring the combinations of such unused synteny mappers and (especially collinear) multiple aligners.

Regarding visualization, many aligners (e.g., [Darling et al., 2010](#)) are internally equipped with, or packaged with, their own viewers, which may be sufficient for usual purposes.

Illustrative Examples

In genome alignment programs, multi-FASTA (MFA) format and multiple alignment format (MAF) files are frequently adopted as input and output, respectively (e.g., [Schwartz et al., 2003](#); [Blanchette et al., 2004](#); [Angiuoli and Salzberg, 2011](#); [Paten et al., 2011](#)). A MFA file contains multiple FASTA-formatted sequence data, each of which consists of a sequence identifier line followed by one or more sequence lines. The FASTA format is used in a wide range of sequence analysis programs, such as sequence alignment, motif discovery and gene finding. See the NCBI web site (see “Relevant Websites section”) for more details on the FASTA format. The MAF, which was also adopted as the submission format in Alignathon (see Section “Alignathon” below) ([Earl et al., 2014](#)), stores a series of MSAs which covers some (or most) parts of entire genomes. Each MSA is expected to consist of genome sequences which are descended from a common ancestral sequence. Depending on what types of genome rearrangements occurred during the course of evolution, MSAs in MAF files show characteristic composition. For instance, duplications lead to MSAs which include more than one sequence from a single species, while deletions lead to MSAs which do not include sequences from a specific species. Moreover, inversions lead to MSAs which include sequences from the reverse strand. See the UCSC Genome Browser web site (see “Relevant Websites section”) for more details on the MAF.

A traditional way to view (the large-scale structure of) a (typically non-collinear) genome alignment is to draw dot-plots ([Gibbs and McIntyre, 1970](#)). A dot-plot graphically visualizes similarities between two nucleotide or amino acid sequences. Pairs of similar regions, which are identified by sequence alignments, are represented as diagonal segments in a dot-plot. [Fig. 1](#) shows the dot-plot of a pairwise alignment between simulated mouse and rat genomes. To create the figure, we downloaded a MAF file, which stores the “correct” alignment of artificial mammalian genomes, from the Alignathon web site (see “Relevant Websites section”) and extracted the pairwise alignment between simulated mouse and rat genomes. Then, we drew its dot-plot by using *maffTools* ([Earl et al., 2014](#)), the HAL package ([Hickey et al., 2013](#)) and a few of our perl and R scripts (available on request to TY). The artificial mammalian genomes were generated by a forward-time simulation of genome evolution. *MafTools* is a toolkit for MAF file (pre)processing, and the HAL package is a toolkit for comparative genome analyses.

A dot-plot is useful to visualize the overall picture of a pairwise genome alignment and infer what types of genome rearrangements occurred during the course of evolution. [Fig. 1](#) also shows typical patterns of diagonal segments in dot-plots and [Fig. 2](#) shows the corresponding parsimonious genome rearrangements. (And [Fig. 3](#) shows some typical patterns that are obscure in [Fig. 1](#).) The more complicated patterns can be understood as combinations of the typical patterns.

Fig. 1 Dot-plot of pairwise alignment between genomes of simulated mouse (simMouse) and rat (simRat). The colored rectangles enclose typical patterns indicative of genome rearrangements. See [Fig. 2](#) for their interpretations. This dot-plot is based on a simulated alignment used as input for Alignathon. Adapted from Earl, D., Nguyen, N., Hickey, G., et al., 2014. Alignathon: A competitive assessment of whole-genome alignment methods. *Genome Res.* 24, 2077–2089.

Fig. 2 Interpretation of diagnostic patterns in dot-plot (Fig. 1). Panels A-D in this figure correspond to the colored rectangles labeled A-D, respectively, in Fig. 1. In panel D, we ignored small-scale rearrangements such as inversions, in order to focus only on the inter-chromosomal translocation and the chromosome fusion/fission. In each panel, an arrow represents a chromosomal region. The arrows are oriented according to the genome on the left, which corresponds to the horizontal axis of the dot-plot (Fig. 1). A black arrow indicates that the region remain unarranged. A colored arrow indicates that the region was rearranged. A dashed line indicates the homology of the region ends that it ties.

Fig. 3 Other diagnostic patterns common in dot-plots. These patterns are generally common in dot-plots, but are missing or obscure in Fig. 1.

Results and Discussion: Evaluation of Alignment Methods

It is utterly crucial to evaluate the accuracy of alignments output by each aligner, because an aligner would be useless unless its resulting alignments are reasonably accurate at least, no matter how fast it can align genome sequences. It is desirable that a third party should evaluate a number of aligners in a fair setting. However, an overwhelming majority of assessments thus far have been conducted by the groups that developed the aligners, thus the results have tended to favor the developers' own aligners. Nevertheless there have been a few studies where independent groups evaluated some aligners (e.g., Margulies *et al.*, 2007; Chen and Tompa, 2010), and a competitive assessment called the "Alignathon", in which a number of aligner-developing groups participated under a considerably fair setting (Earl *et al.*, 2014). In this section, we discuss these evaluations, after briefly discussing major evaluation methods.

Major Evaluation Methods

It is notoriously difficult to evaluate the accuracy of a genome alignment, because we do not know the “correct” alignment that resulted from the true evolution of the genome sequences, and that can be used as the “gold standard” to be compared against alignments reconstructed by aligners. Therefore, it is inevitable to settle for some surrogate methods for evaluating the alignment accuracy. According to [Earl et al. \(2014\)](#), such evaluation methods conducted thus far can be classified into four broad categories: (i) those using simulation, (ii) those using expert information, (iii) those using direct statistical assessment, and (iv) those that assess how well an alignment functions for a downstream analysis. Each of these methods has its own pros and cons. Here, we briefly summarize the discussions on them by [Earl et al. \(2014\)](#). (See [Iantorno et al., 2014](#) for a more comprehensive review on the topic).

In category (i), researchers create some “correct” alignments via simulations of genome evolution, and compare them with alignments reconstructed by aligners. A merit of this category is that we know the “correct” alignment that can be compared to the reconstructed ones. Its major demerit is that it is not certain whether the simulation adequately reflects the evolutionary forces operating on the true genomes.

In category (ii), researchers evaluate reconstructed alignments using some expert biological information, such as annotations of functional elements, structural alignments, and expertly curated alignments (e.g., [Blackshields et al., 2006](#); [Wilm et al., 2006](#); [Kemena et al., 2013](#)). A merit of this category is that the methods provide objective evolutionary contexts derived from the real genomes, giving us some relief. Its demerit is that each method may address only a small fraction of the alignment and that each method may itself rely on other forms of inference, thus making it uncertain whether the assessment is indeed correct or not.

In category (iii), evaluations are made using statistical measures that indicate the reliability (or uncertainty) of each portion of reconstructed alignments (e.g., [Prakash and Tompa, 2007](#); [Landan and Graur, 2008](#); [Penn et al., 2010](#); [Kim and Ma, 2011](#); [Chang et al., 2014](#)). A merit of this category is that we can assess the complete alignments of real sequences. Its demerit is that, unless carefully calibrated using gold standard alignments, they are only a proxy to a true assessment of accuracy.

In category (iv), aligners are assessed, typically by biologists, according to intuition or downstream analyses. Because of their ad-hoc nature, these assessments are difficult if not impossible to generalize from. For whole-genome alignments (WGAs), their effects were assessed, e.g., on de novo ncRNA predictions ([Gorodkin et al., 2010](#)) and on the prediction of conserved elements ([Margulies et al., 2007](#)).

Before Alignathon

Before the Alignathon ([Earl et al., 2014](#)) took place, there have been relatively few independent or community organized assessments of WGA pipelines. Notable among such evaluations are the assessment as a part of the ENCODE pilot project ([Margulies et al., 2007](#)) and the evaluation by [Chen and Tompa \(2010\)](#).

As a part of the ENCODE pilot project ([Birney et al., 2007](#)), [Margulies et al. \(2007\)](#) aligned sequences orthologous to the ENCODE-regions obtained from 23 mammalian species (including human and two non-eutherian mammals). They used four pipelines (each represented by its major components): TBA/BLASTZ (abbreviated as TBA) ([Blanchette et al., 2004](#); [Schwartz et al., 2003](#)), MLAGAN/Shuffle-LAGAN (abbr. as MLA-GAN) ([Brudno et al., 2003b,c](#); [Dubchak et al., 2009](#)), MAVID/Mercator (abbr. as MAVID) ([Bray and Pachter, 2004](#); [Dewey, 2007](#)), and Pecan ([Paten et al., 2008a, 2009](#)). (NOTE: The Pecan pipeline actually used Shuffle-LAGAN as a pre-processor, because Pecan is a collinear aligner.) Their comparisons of the four pipelines revealed large-scale consistency but substantial differences in terms of small genomic rearrangements, sensitivity (sequence coverage) and specificity (alignment accuracy).

In terms of the above classification, their alignment assessments belong to category (ii). Because their alignments are of real genomic sequences, they cannot be compared with the true alignments, which are inherently unknown. Therefore [Margulies et al. \(2007\)](#) used some surrogates for sensitivity and specificity. For sensitivity, they used two surrogates. One is the coverage of annotated protein-coding sequences in each alignment. And the other is the coverage of ancestral repeats (ARs) in each alignment. Overall, these coverage measures varied considerably among different alignments: MAVID showed the smallest coverage, MLAGAN showed the largest coverage for protein-coding sequences, and Pecan showed the largest coverage for ARs. For specificity as well, they used two surrogates. One was the “*Alu* exclusion”, which is how well each pipeline can avoid the false-positive alignments of human *Alu* elements to any non-primate mammalian sequence. (It is well known that *Alu* elements are specific to primates.) And the other was the substitution periodicity in coding regions, which takes advantage of the fact that the third codon positions are enriched in synonymous sites and thus prone to substitutions. TBA was the most specific in terms of both measures, and Pecan almost tied with TBA in terms of the substitution periodicity. MLAGAN was the least specific in terms of the *Alu* exclusion, and MAVID was the least specific in terms of the substitution periodicity.

[Chen and Tompa \(2010\)](#) also evaluated the alignments of the ENCODE-regions generated by the aforementioned four pipelines. One difference from the study of [Margulies et al. \(2007\)](#) is that [Chen and Tompa \(2010\)](#) included non-mammalian vertebrates as well. (Like [Margulies et al., 2007](#), they analyzed the pairwise alignments of human and each non-human species extracted from the reconstructed multiple genome alignments.) Another difference is that the evaluation of [Chen and Tompa \(2010\)](#) was more comprehensive, involving all sites of the aligned sequences. The evaluation results were also broken down into four location categories, namely, coding, untranslated (UTR), intronic, and intergenic. In the comparison of the alignments generated by TBA, MLAGAN, and MAVID, the degree of agreement substantially decreased from coding to non-coding regions, and as the evolutionary distance between species increases. Their alignment evaluation belongs to category (iii). As a surrogate for the

sensitivity, they examined the coverage of each alignment, and to evaluate the alignment accuracy, they used a statistical measure computed via StatSigMa-w (Prakash and Tompa, 2007). Regarding the coverage, the results were consistent with those of Margulies *et al.* (2007), that is, MLAGAN showed the highest coverage and MAVID showed the lowest coverage. For every pipeline, the coverage decreased as the divergence between species increases, especially for non-coding regions. Regarding the alignment accuracy, Pecan was the most accurate, and MLAGAN was the least accurate. TBA was nearly as accurate as Pecan for eutherian mammals, but was substantially less accurate than Pecan for more distant species. For every pipeline, the accuracy suddenly dropped from eutherian mammals to more divergent species, and from coding to non-coding regions. These results indicated that reconstructing whole-genome multiple sequence alignments remains a challenge, especially for non-coding regions and distant species (like non-eutherian mammals and non-mammalian vertebrates). One caveat given by Chen and Tompa (2010) is that their accuracy measure based on StatSigMa-w may somewhat overestimate the true accuracy; thus, the reconstructed alignments should have more misalignments than their accuracy measure indicates. Chen and Tompa (2010) attributed this to StatSigMa-w's conservative calls of suspicious regions in the alignment.

Alignathon

The Alignathon (Earl *et al.*, 2014) is a competitive evaluation of whole-genome alignment tools in which teams submitted their alignments and then assessments were performed collectively after all the submissions were received. As the input, they used three data sets. Two were simulated DNA data: one based on the phylogeny of four primates (human, chimpanzee, gorilla, and orangutan), and the other based on the phylogeny of five eutherian mammals (human, mouse, rat, dog, and cow). And the remaining one was the real DNA sequence data, comprised of 20 fly genomes. In total, the Alignathon received 35 submissions, which were generated by 12 different alignment pipelines. The 12 pipelines they used were: three pipelines used by genome browsers (VISTA-LAGAN for the VISTA Browser (Frazer *et al.*, 2004; Dubchak *et al.*, 2009), MULTIZ for the UCSC Genome Browser (Miller *et al.*, 2007; Meyer *et al.*, 2013), and Pecan and EPO for the Ensembl Browser (Paten *et al.*, 2008a, 2009; Flicek *et al.*, 2013); seven standalone WGA tools (progressiveMauve (Darling *et al.*, 2010), TBA (Blanchette *et al.*, 2004), Cactus (Paten *et al.*, 2011), Mugsy (Angiuoli and Salzberg, 2011), Robusta (Notredame, 2012), which combines results from multiple stand-alone tools, PSAR-Align (Kim and Ma, 2014), which was used to re-align MULTIZ-based alignments and the pipelines of AutoMZ and GenomeMatch teams. (Specific settings of the pipelines are described in the Supplemental material of Earl *et al.*, 2014).

For each reconstructed alignment of the simulated data, they computed the “precision” (the proportion of aligned pairs of nucleotides in the reconstructed alignment that are also true) and the “recall” (the proportion of aligned pairs of nucleotides in the true alignment that are also reconstructed). And they also defined the F-score as the harmonic mean of precision and recall. This evaluation belongs to category (i) in Section “Major Evaluation Methods”. They found that many of the submissions were able to align primate data set with both relatively high recall and precision, consistently across annotation types. For the mammalian simulations, they found a much wider variation of results, both between alignments and between different annotation classes. Especially, recall varied much more widely than precision, which was relatively high for most aligners. Among submissions, Cactus showed the highest F-score. Generally, submissions performed best in genic regions and most poorly in repetitive regions. And precision and recall values got lower as the distance between species increased.

For each reconstructed alignment of the real genomic data, the aforementioned recall or precision cannot be computed. Thus, they resorted to a statistical evaluation (belonging to category (iii) in Section “Major Evaluation Methods”). As a proxy to the precision, they computed the *PSAR-precision* based on the output of PSAR statistical alignment tool (Kim and Ma, 2011). As a proxy to the recall, they used the *coverage*. Then, as a proxy to the F-Score, they also defined the *pseudo F-Score* as the harmonic mean of PSAR-precision and coverage. Before applying these statistical measures to alignments of the real fly genomes, they examined their consistency with the measures for simulations, after calculating both for the simulated alignments. In the simulated mammals, they found a very good, linear correlation between recall and coverage ($r^2=0.984$), but no linear correlation between PSAR-precision and precision. Regarding the F-Score and the pseudo F-Score, they linearly correlated strongly ($r^2=0.975$), likely because recall varied much more widely among the alignments than precision. Then, using the statistical measures, they evaluated the reconstructed alignments of the real 20 fly genomes. In general, they saw good concordance between the fly and simulated results.

These results are more or less consistent with those of the aforementioned two evaluations (Margulies *et al.*, 2007; Chen and Tompa, 2010). In addition, the Alignathon produced some interesting results. For example, direct comparisons between the submitted alignments suggested that sharing the same synteny mapper influenced the results more strongly than sharing the same (collinear) synteny block aligner. Moreover, they found that no pipelines except Cactus can capture significantly nonzero duplications into the reconstructed alignment. In their conclusions, they cautioned against overinterpretation of the results because of the limitations of their assessment methods, and they encouraged more independent lines of assessment: more simulations, more statistical assessments, and assessments at different scales, etc.

Future Directions

In the past two decades, vigorous efforts and dedication of many researchers have greatly improved genome alignment methods in terms of their speed, accuracy, and scope (such as the number of input sequences, evolutionary distance, the range of acceptable mutations, etc.). However, as the field of comparative genomics gets more advanced and more and more genome sequences become available, genome aligners will need to become faster, more accurate, more robust and more flexible. Indeed,

researchers eagerly attempt to improve the aligners' performance even today (e.g., Frith and Kawaguchi, 2015; Uricaru *et al.*, 2015; Mai *et al.*, 2017; Suarez *et al.*, 2017). Here, we discuss a few representatives among possible future directions that the study of genome alignment should head for.

Pursuit of Further Space- and Time-Efficiency

Genome alignment methods have become substantially efficient in computational time and space (memory) requirement (e.g., Paten *et al.*, 2009; Nakato and Gotoh, 2010; Angiuoli and Salzberg, 2011). However, as the number of available genome sequences has still been growing exponentially (e.g., Margulies and Birney, 2008; Dewey, 2012; Earl *et al.*, 2014; Thompson, 2016a), the demand also keeps growing for a method that can align a large number of genomes in a reasonable amount of time (e.g., Dewey, 2012).

Regarding the multiple alignment of small to medium size sequences, some new heuristic methods have recently been proposed that enable the alignment of thousands to even millions of sequences (e.g., Katoh and Toh, 2007; Sievers *et al.*, 2011; Mirarab *et al.*, 2015; Nguyen *et al.*, 2015). (For a review of such aligners, see, e.g., Thompson, 2016b and Warnow (2017)). By combining in some way these heuristics with the heuristics that have been developed for genome alignment thus far (such as "anchoring" (e.g., Delcher *et al.*, 1999; Höhl *et al.*, 2002; Brudno *et al.*, 2003a), also known as the "divide-and-conquer" strategy for a long alignment (e.g., Kryukov and Saitou, 2010)), it may be possible to develop aligners that can align, e.g., hundreds to thousands of genomes in a reasonable amount of time. A framework using the meta-alignment methods, Crumble and Prune (Roskin *et al.*, 2011), would probably provide a good starting point for such efforts. And it would also be important to extend the framework to non-collinear aligners.

Pursuit of Further Alignment Accuracy

Although the accuracy of genome aligners have improved considerably (e.g., Chen and Tompa, 2010; Earl *et al.*, 2014), there is still big room for improvement. The problem of alignment accuracy may be broadly divided into two subproblems: (a) it seems that the specificity (or precision) have reached a plateau that is still considerably below (near) perfection; (b) the sensitivity (or recall) is far below perfection even with the current best aligner (e.g., Cactus). The subproblem (a) may be overcome, e.g., by (1) incorporating information other than the primary structures (i.e., the strings of bases) of DNA sequences (reviewed, e.g., in Kemena and Notredame, 2009), and by (2) taking account of the intrinsic stochasticity of genome evolution more seriously. The subproblem (b) may be addressed by (3) more accurate detection of genome rearrangements and duplications. And both subproblems may be partly solved by (4) properly dealing with errors in sequencing and assembly as well as false-positive matches. Let us discuss them in more details.

- (1) One possible reason for the imperfect specificity of current aligners is that the scoring schemes for them (including the quite sophisticated probabilistic scoring (e.g., Paten *et al.*, 2008b; Bradley *et al.*, 2009; Paten *et al.*, 2009)), are mostly based on simple "space-homogeneous" models, which provide homogeneous mutation rates along the sequence. In reality, it is well-known that functionally important regions evolve more slowly than neutral regions, and that evolution tend to conserve features related to functions (such as the secondary and tertiary structures of proteins and RNA genes) than the primary structures. Therefore, if these functional features are known prior to the alignment (via some experiments), such information could help reconstruct more accurate genome alignments (e.g., Kemena and Notredame, 2009). One implementation of this idea is via template-based aligners, which align sequences guided by templates that represent such functional information (e.g., Pei *et al.*, 2008; Wilm *et al.*, 2008; Katoh and Toh, 2008).

A possible challenge would be how to make template-based aligners scale to genome alignments, because they tend to be slower than simple aligners. Besides, this method would work only for functional regions with experimental information, which generally account for only a small fraction of genome sequences.

- (2) Another possible reason for the imperfect specificity is that the evolutionary processes are inherently stochastic; in consequence, a true alignment resulting from an evolutionary process is very frequently *not* optimal even under the ideal objective score function, i.e., (the logarithm of) the probability that natural evolutionary processes give rise to the alignment. To support this idea, it was shown that taking account of the stochasticity of evolution substantially improves the accuracy and consistency of the pairwise sequence comparisons (e.g., Lunter *et al.*, 2008; Cartwright, 2009). Moreover, a simulation study demonstrated that, in a (near) majority of errors in multiple sequence alignments, the true alignments indeed do *not* optimize the alignment probabilities calculated with the particular evolutionary model used for the simulations. These results strongly suggest that, in order to further improve the alignment accuracy, it is essential to present the stochastic nature of evolutionary processes as well, rather than merely attempting to reconstruct a single optimal alignment.

Attempts to cast the sequence alignment problems into a statistical framework with some probabilistic modelling of gaps (often referred to as "statistical alignment" (Hein *et al.*, 2000)) started with two groundbreaking studies (Bishop and Thompson, 1986; Thorne *et al.*, 1991). Then, the efforts extended to various problems (including multiple sequence alignments) using Hidden Markov Models (HMMs) (including transducers) (e.g., Holmes and Bruno, 2001; Holmes, 2003; Bradley and Holmes, 2007; Miklós *et al.*, 2009; Herman *et al.*, 2015; Rivas and Eddy, 2015). Currently, HMMs are the dominating models in the study of statistical alignment, partly because they are convenient enough to enable various dynamic programming algorithms (for, e.g.,

finding an optimum alignment and calculating the posterior probabilities of matches) (Durbin *et al.*, 1998), and partly because they are flexible enough to accommodate site-specific mutation rates (e.g., Durbin *et al.*, 1998; Rivas and Eddy, 2015) and mixed geometric length distributions of insertions/deletions (indels) (e.g., Miklós *et al.*, 2004; Do *et al.*, 2005; Lunter *et al.*, 2008; Bradley *et al.*, 2009; Paten *et al.*, 2009), which can approximate reasonably (up to dozens of residues) the power-law indel length distributions that have been repeatedly observed in molecular evolutionary analyses (e.g., Gonnet *et al.*, 1992; Benner *et al.*, 1993; Gu and Li, 1995; Zhang and Gerstein, 2003; Chang and Benner, 2004; Yamane *et al.*, 2006; Fan *et al.*, 2007). (For a recent review on these developments, see, e.g., Holmes, 2017).

Unfortunately, however, some recent studies revealed the limitations of alignment methods based on HMMs (e.g., Darling *et al.*, 2010; Rivas and Eddy, 2015).

These results imply that, in order to pursue near perfect accuracy, we will ultimately need a probabilistic aligner that is based on a genuine sequence evolutionary model with realistic instantaneous insertion/deletion rates, such as the substitution/insertion/deletion models (Miklós *et al.*, 2004). (NOTE: Roughly speaking, in a genuine sequence evolutionary model, the probability of an evolutionary process of a sequence is calculated as a multiplicative accumulation of infinitesimal-time transition probabilities of the states of an entire sequence over a given time interval). However, there still remain some technical challenges, such as the development of adequately fast algorithms, to achieve this crucial goal of developing a probabilistic aligner based on a genuine evolutionary model of a sequence.

- (3) In most of the current genome alignment methods, detecting genome rearrangements and duplications is the job of a separate synteny mapping program or the synteny mapping component of a non-collinear aligner. These methods have been based on heuristics, including the graph construction and modification procedures, and a number of involved parameters had to be adjusted via an extensive trial and error. Therefore, more principled methods based on probabilistic or, ideally, evolutionary modelling of synteny mapping may improve the accuracy (both sensitivity and specificity) of the detection of rearrangements and duplications (as suggested, e.g., by Dewey, 2012; Ghiurcuta and Moret, 2014). (Although some maximum likelihood methods have already been proposed (e.g., Hachiya *et al.*, 2009), the underlying probabilistic models seem somewhat heuristic). Besides, because synteny blocks (or regions of homologous collinearity) are products of inherently stochastic evolutionary processes, the true synteny maps may not optimize even the true occurrence probability, as in the case of collinear alignments. Therefore, also in synteny mapping, it will become essential to take adequate account of inherent stochastic nature of evolution, for example by presenting multiple near-optimal solutions and their probabilities (as suggested, e.g., by Dewey, 2012).

Probably, the best way would be to construct a genuine stochastic evolutionary model of a genome that incorporate rearrangements and duplications in addition to substitutions, insertions, and deletions, and to establish a probabilistic framework for synteny mapping based on the model. Thus far, some evolutionary models of genome rearrangements (and duplications) seem to have been proposed (e.g., Tesler, 2002; Ma *et al.*, 2008; Lin and Moret, 2011; Da Silva *et al.*, 2012; Shao *et al.*, 2013; Ghiurcuta and Moret, 2014; Braga and Stoye, 2015). To the best of our knowledge, however, there have been no genuine stochastic evolutionary models describing genome rearrangements and duplications applicable to the genome alignment problem. If such genuine stochastic evolutionary models are developed in the future, they may be applied to the problem of “statistical whole-genome alignment”, including “statistical synteny mapping”. We do admit that lots of challenges lie ahead in order to achieve this formidable goal. Especially, in addition to some methodological breakthroughs to enable the efficient computation of the likelihoods of possible synteny mappings, it should become indispensable to determine feature-dependent rates of rearrangements and duplications via data analyses that are more extensive and more meticulous than the past ones (e.g., Kent *et al.*, 2003; Church *et al.*, 2009; Mills *et al.*, 2011).

- (4) Because errors in the sequencing and assembly processes are likely to cause serious errors in the final alignment, dealing with these errors prior to or during the alignment process could significantly improve the alignment accuracy (as discussed, e.g., in Pevzner and Tesler, 2003; Margulies and Birney, 2008). An almost equally important issue is the handling of false-positive matches (or seeds) that are erroneously chosen as anchors. Traditionally, chaining (or clustering) algorithms (e.g., Bourque *et al.*, 2004; Ohlebusch and Abouelhoda, 2005) have served to filter potentially false-positive matches, and more recently, some graph-based non-collinear aligners and synteny mappers seem to deal with these problems by “cleaning” or “smoothing” the graphs via some intuition-based heuristics (e.g., Paten *et al.*, 2008a; Pham and Pevzner, 2010). Theoretically, these problems could also be addressed in a more principled way, if we model these errors as some stochastic processes (e.g., Verzotto *et al.*, 2016). And the error-handling and non-collinear alignment (or synteny mapping) might be performed in a unified manner if we merge the stochastic model of the errors with the genuine stochastic evolutionary model of genomes, as in some population genetic studies.

Closing Remarks

Genome sequence alignment is a cornerstone of comparative genomic study. Unlike traditional alignment of e.g., protein coding sequences or RNA sequences, genome alignment has been extremely challenging because of the sheer sizes of genome sequences and of the fact that genome sequences have undergone rearrangements such as inversions, translocations, and duplications during their evolution, in addition to substitutions, insertions, and deletions that have been dealt with by traditional alignment methods. Over the past two decades, a number of methodological innovations have greatly advanced the genome alignment methods, to

cope with these challenges and to improve the accuracy of the resulting alignments. However, as the number of sequenced genomes has been growing exponentially, and as further accurate comparative genomic analyses have been getting required, the genome alignment methods must still keep improving, e.g., via new strategies discussed in the “Future Directions” section.

Phylogenetic Footprinting

Hiroyuki Toh, Kwansei Gakuin University, Sanda, Japan

Introduction

Identification of regulatory motifs such as transcription factor binding sites in genomic non-coding regions is one of the approaches to understand the mechanisms of gene expression regulation. Recent progress of the sequencing technologies such as 'ChIP-Seq' has made it possible to identify the genome-wide identification of regulatory regions, although such 'wet' studies are not enough to reveal overall regulatory motifs in a genome. The development of the sequencing technologies has also contributed to the accumulation of genomic sequences from various organisms. Thereby, a wide variety of computational approaches for the prediction of regulatory motifs with the sequence data have been developed to complement or accelerate the experimental studies on the gene expression regulation. The computational approaches are roughly classified into two types, which are referred to as 'single species, multiple genes' approach and 'single gene, multiple species' approach, respectively (Wang and Stormo, 2003). The former examines the regulatory motifs of multiple genes in a single genome, which are indicated to be regulated under the same regulatory mechanism. The latter analyzes the regulatory motifs of an orthologous set of a single gene from multiple organisms, in which the conservation of the regulatory mechanism for the orthologous genes from different organisms is implicitly assumed. 'Phylogenetic footprinting' belongs to the latter, the 'single gene, multiple species' approach.

Phylogenetic Footprinting and Related Approaches

Phylogenetic footprinting was first developed by Tagle *et al.* (1988) to predict *cis*-regulatory motifs of embryonic ϵ and γ globin genes of primates. The idea behind the method is quite simple. The motifs involved in gene expression regulation are assumed to be subject to strong functional constraints. Suppose that a residue in such a region is replaced with other residue. If the mutation has ill effects on the regulatory mechanism, the progeny with the mutation would be rapidly excluded from a population by negative selection or purifying selection. By that means, genomic regions responsible for regulatory functions are more conserved than non-coding regions without function. So, it is the first step of phylogenetic footprinting to collect nucleotide sequences of the orthologous non-coding regions from multiple species. For example, the 5' upstream region of a gene is often used for the analysis, although *cis*-regulatory elements are not always restricted in the 5' regions. Next, a multiple alignment of the nucleotide sequences thus collected is made. Standard tools for global multiple alignment can be used for this step. Finally, the degree of conservation was evaluated at each site or with a sliding window. Highly conserved non-coding regions detected from the alignment are predicted as putative regulatory motifs (see Fig. 1). Several methods to improve the performance of phylogenetic footprinting have been reported. For example, an approach to use statistical alignment instead of a fixed alignment was proposed for phylogenetic footprinting (Satija *et al.*, 2008). A Bayesian method named BigFoot (Satija *et al.*, 2009), which was developed as an extension of the method with the statistical alignment, used Markov chain Monte Carlo sampling for both alignment and conserved regions.

There are several limitations in phylogenetic footprinting. One of them is related to sequence divergence. Moderate sequence divergence can highlight the conserved regions in a multiple sequence alignment. When sequences under consideration are highly diverged, however, an inaccurate alignment may be generated. Regulatory motifs are often short, comparing to the lengths of the

Fig. 1 Standard flowchart of phylogenetic footprinting.

entire sequences under examination. In that case, even if each sequence has the regulatory motif, they may not be correctly matched each other in the alignment, which leads to failure in detection of the regulatory motifs. Inversely, when sequences under consideration are closely related, the footprinting procedure described above would not work well to detect regulatory motifs, since the number of substituted sites in the closely related sequences is too small to reveal conserved sites. The other limitation is that the implicit assumption behind the analysis does not always hold true. The regulatory motifs have been sometimes deleted or added by the lineage-specific manner. Therefore, complete conservation of regulatory motifs among all the collected orthologous sequences is not always expected. Various methods have been developed to overcome the limitations of the original phylogenetic footprinting.

The problem related to high sequence divergence has been addressed by searching for the short segments shared by the collected orthologous non-coding sequences, instead of making a global multiple alignment. The idea is the same as those of the motif discovery tools for the 'single species, multiple genes' approach. For example, McCue *et al.* (2001) used Gibbs sampler (Lawrence *et al.*, 1993) as a tool for phylogenetic footprinting to detect motifs from bacterial genomes. However, the subject of the motif discovery tools for the 'single species, multiple genes' approach is different from that of the phylogenetic footprinting. The set of non-coding regions of the genes under the same regulatory mechanism, which are indicated by co-expression or immunoprecipitation, is the subject of the approach (Wang and Stormo, 2003). That is, the genes used for the analysis are not always homologous and basically independent. Blanchette and Tompa (2002) pointed out a problem to apply the motif discovery tools for the 'single species, multiple genes' approach to phylogenetic footprinting. Most of the motif discovery tools are designed to find motifs from a set of independent sequences as described above. However, the subject of phylogenetic footprinting consists of orthologous sequences. Consider a set of orthologous sequences, in which the majority of the sequences are closely related to each other and only a few sequences are distantly related to the majority. Then, the patterns present in the closely related sequences would be highly weighted, even if the patterns were not conserved in the distantly related sequences. Therefore, such taxonomic bias should be removed for the motif discovery from the orthologous sequences. FootPrinter (Blanchette *et al.*, 2002; Blanchette and Tompa, 2003), PhyME (Sinha *et al.*, 2004), PhyloGibbs (Siddharthan *et al.*, 2005), and a phylogenetic Gibbs sampler (Newberg *et al.*, 2007) are the tools for phylogenetic footprinting developed by introducing the idea.

A different approach is required when only closely related sequences are available. Boffelli *et al.* (2003) developed a method referred to as 'phylogenetic shadowing' to identify primate specific functional regions in human genome by comparing closely related primate sequences. In the analysis, the log likelihood ratio between the fast and slow mutation models is calculated for each column of the alignment with the phylogenetic tree and mutation rates for 'non-conserved' and 'conserved' regions estimated from a training set. A low log likelihood ratio indicates that the corresponding site is subject to strong constraints. Later, the group extended their method to develop an online shadowing tool, eShadow (Ovcharenko *et al.*, 2004). Ray *et al.* (2008) devised a new shadowing method named CSMET by combining a probabilistic graphical model with a hidden Markov model.

The problem of addition or deletion of regulatory elements is an important problem. Actually, it is considered that such events may have occurred by lineage specific manners. The problem is explicitly treated in an algorithmic method developed by Blanchette *et al.* (2002).

There are studies to integrate phylogenetic footprinting with the motif discovery methods for the 'single species, multiple genes' approach. Wang and Stormo (2003) first identified conserved regions from the alignments of non-coding regions for the co-regulated genes. The conserved regions are expressed as profiles and are compared the profiles from different co-regulated genes to identify the shared motifs. ConSite is also a tool to predict transcription factor binding sites by integrating phylogenetic footprinting with a motif discovery method (Lenhard *et al.*, 2003). PFR-Sampler can integrate the phylogenetic footprints with the information of co-regulation of genes with the Markov chain discrimination algorithm to identify the similar phylogenetic footprinted regions (PFRs) near the co-regulated genes (Grad *et al.*, 2004). Bigelow *et al.* (2004) developed a pipeline named CisOrtho, in which non-coding sequences from two species under consideration are first scanned by a weight matrix respectively. Then, the hit regions thus obtained are compared to identify the conserved motifs between the two species. The latter step was regarded as phylogenetic footprinting. TargetOrtho is an expanded version of CisOrtho (Glenwinkel *et al.*, 2014). One of the interesting expansions is the introduction of relaxed definition of motif conservation based on the alignment-free approach (Elemento and Tavazoie, 2005; Gordán *et al.*, 2010). Probabilistic frameworks to integrate phylogenetic footprinting and motif discovery are described in a review by van Nimwegen (2007).

Some of the online tools currently available are listed in Table 1.

Examples of Application of Phylogenetic Footprinting

As described above, phylogenetic footprinting was first applied to the prediction of the *cis*-regulatory motifs of embryonic ϵ and γ globin genes of primates in 1988 (Tagle *et al.*, 1988). The same group continued the studies of the *cis*-regulatory regions of globin genes with phylogenetic footprinting. In 1992, they identified several conserved sequences in the 5'-flanking regions of the γ and ϵ globin genes by phylogenetic footprinting, some of which were suggested to function as repressors by experiments (Gumucio *et al.*, 1992). They also applied the method to the 5' region of the ϵ globin gene to identify conserved sequences in 1993. The combination of the computational analysis with the experimental study revealed the complex binding profile of trans factors in the 5' region of the ϵ globin gene (Gumucio *et al.*, 1993).

After the pioneering works, the method has been applied to various organisms. Sauer *et al.* (2006) evaluated the validity and usability of phylogenetic footprinting through the comparison of human and rodent based on the known 2678 transcription factor binding sites. They discussed the dependency of phylogenetic footprinting on the criterion of conservation, alignment algorithm and the types of transcription factors. von Bubnoff *et al.* (2005) compared the upstream regions of *Xenopus* and human *Vent2* genes to identify a 21 bp conserved sequence. The conserved sequence overlaps the known BMP response element. Their experimental study suggested the necessity and sufficiency of the conserved sequence for the BMP responsiveness. Matsunami *et al.* (2010) applied the phylogenetic footprinting to the identification of the conserved non-coding regions among the paralogues of Hox clusters generated by the 2-round whole genome duplications. Cliften *et al.* (2003) compared six *Saccharomyces* genomes. They found that some of the conserved sequences identified by the analysis are present in the upstream of the genes with similar annotations, similar expression patterns, or are in the regions bound by the same transcription factor. Buchanan *et al.* (2004) compared the 5'-non-coding regions of *rab16/17* genes from sorghum, maize, and rice to identify the *cis*-regulatory elements. Lutz *et al.* (2017) aligned the genomic sequence of *Arabidopsis* *FLM* (*FLOWERING LOCUS M*) with those of *FLM* homologues from five other *Brassicaceae* species, together with that of its closest homologue *MAF3*, for the phylogenetic footprinting analysis. They found conserved non-coding sequences in the promotor region and the first intron. They revealed that the conserved regions thus detected are involved in the basal expression of the gene by experimental studies. Aceto *et al.* (2010) combined the motif search with the phylogenetic footprinting to identify putative transcription factor binding sites corresponding to the conserved 5'-non-coding sequences of the *OrcPI* gene from the orchids *Orchis italica*. The homologous non-coding sequences from two other monocots, *Lilium regale* and *Oryza sativa*, and one dicots, *Arabidopsis thaliana* were used for the footprinting analysis. Phylogenetic footprinting is applied not only to eukaryotes, but also to prokaryotes (Neph and Tompa, 2006; Katara *et al.*, 2012; Liu *et al.*, 2016).

Phylogenetic shadowing is also widely utilized for the detection of conserved non-coding regions. The method was first introduced by Boffelli *et al.* (2003). They compared the sequences of primates consisting of Old World monkeys, New World monkeys and hominoids, to identify primate specific regulatory elements and exon boundaries. Clark *et al.* (2005) applied the phylogenetic shadowing to the identification of the conserved non-coding regions of *CAPN10* (calpain 10), a genetic factor of type 2 diabetes, through the comparison of 10 primates sequences. They discussed the possibility that some of the detected regions may be associated with the expression of *CAPN10*.

What phylogenetic footprinting does is to identify the conserved or slowly evolving regions. So, the application of the method is not restricted to the detection of regulatory motif. Actually, both phylogenetic footprinting and shadowing are applied not only to regulatory motif discovery but also to the detection of microRNA genes (Berezikov *et al.*, 2005; Gao *et al.*, 2013).

The examples described above are quite limited, and there are more literatures on the applications of phylogenetic footprinting and shadowing. However, the term, "phylogenetic footprinting" or "phylogenetic shadowing", is often missing from abstracts of the literatures. The search with combination of keywords such as "conservation" and "regulatory elements" could lead to the literatures of the studies with phylogenetic footprinting or shadowing.

Concluding Remarks

The idea behind the phylogenetic footprinting and the development of the approach were described in this section. All the methods described above utilize only sequence data to predict regulatory elements as conserved non-coding regions. However, an insightful review by Maeso *et al.* (2013) suggests novel directions to predict regulatory elements beyond the sequence-based techniques of current phylogenetic footprinting. Metazoans share basic developmental process such as genetic toolkits. So, it was expected that the *cis*-regulatory elements related to the process are conserved across animal phyla. However, it turned out that the prediction of *cis*-regulatory elements based on sequence conservation such as phylogenetic footprinting is difficult when genomes of different phyla are compared. They stressed that the approach with the next generation sequencer (NGS) such as ChIP-seq and DNase I footprint is efficient for the genome-wide identification of *cis*-regulatory elements. They also suggested the possibility that the functionally equivalent *cis*-regulatory elements occupy similar syntenic positions, and that the inclusion of such positional information is useful to avoid the false positives of sequence-based predictions. The introduction of NGS data and the syntenic information could shed new light on the conservation and evolution of *cis*-regulatory elements across phyla.

Introduction

It has long been a question whether the genome has spatial organization and to what extent it influences its function. A critical part of modern medicine might depend on our understanding how the genome organization works in the context of replication and gene expression and its regalia of promoters, enhancers, the DNA associated proteins, including RNA polymerase II (Rpol2), and the spliceosome apparatus (SA). The most crucial question is does gene expression depend on the spatial proximity of the promoters, inhibitors, and enhancers? What role, if any, does proximity play? How do Rpol2 and SA operate in conjunction with unraveling the nucleosome and how does this factor into exon/intron splicing? How does a developing organism determine what genes to express and when and how is that controlled? What happens when proper functioning of the cell fails? There are many unanswered questions in the field of genomics; nevertheless, recent research has opened the door to at least a partial understanding of some of these important issues.

Progress in our understanding of nuclear architecture has advanced due to the ongoing development of various imaging techniques like FISH (fluorescent in situ hybridization), confocal microscopy (O'Connor, 2008; Wurtele and Chartrand, 2006; Wang *et al.*, 2015; Lomvardas *et al.*, 2006; Rosa *et al.*, 2010; Fraser *et al.*, 2015; Giorgetti *et al.*, 2014; Muller *et al.*, 2010) and electron microscopy (Ou *et al.*, 2017) as well as in contact mapping techniques especially chromatin conformation capture (3C) method (Wurtele and Chartrand, 2006; Dekker *et al.*, 2002; Lomvardas *et al.*, 2006) and various techniques derived from 3C; e.g., Hi-C (Rao *et al.*, 2014; Lieberman-Aiden *et al.*, 2009; Jin *et al.*, 2013; Fraser *et al.*, 2015; Dixon *et al.*, 2012), ChiA-PET (Ji *et al.*, 2016; Tang *et al.*, 2015; Li *et al.*, 2017; Fullwood *et al.*, 2009a) or HiChIP (Mumbach *et al.*, 2016). The details of these methods are available elsewhere (Fraser *et al.*, 2015) and in this review we provide only a brief summary regarding some of these techniques. There is a growing consensus that there is considerable (quasi) organization in the arrangement of eukaryotic chromatin in the nucleus and that the chromatin fiber exhibits a considerable degree of compartmentalization.

It should seem puzzling that a 6 billion base pair (bp, 6 Gbp) somatic chromatin fiber arranges itself in such a way that it does not become tied up in knots, and organizes itself efficiently into 46 chromosomes in a repeatable way during its mitosis phase. As a thought experiment, consider what happens to a pair of earphone when dumped into a carry bag with other stuff and rattled around for a while. The earphones quickly become tangled into at least one knot. Moreover, the cell itself is a highly dynamic yet in many ways disordered system too. How then does a 6 Gbp genome keep from getting thoroughly tangled up like the earphones yet at the same time remain only partially ordered?

In this review, we will look briefly through the levels of the DNA organization starting from the double stranded DNA (dsDNA) up to the interactions between different parts of the chromatin. We will briefly discuss some of the current experimental and computational methods aiming to predict chromatin conformations.

Chromatin 3D Interactions: Short Range to Long Range

Here we take a progressive picture of chromatin from the components at the coarse-grained scale of histones (~nm) to the long range binding between distant parts of the chromatin, which extends to about 1 Mbp and perhaps even as large as 3 Mbp.

The Local Structure of the Nucleosomes

Chromatin is a complex heteropolymer comprised of many different components. Double-stranded DNA (dsDNA) in eukaryotic organisms is bundled into packages called nucleosomes. The dsDNA wraps about an octamer of core histone proteins (roughly 7/4 turns; about 147 bp) like on a solenoid (Fig. 1). The octamer contains a tetrameric core of H3 and H4 proteins bound together and forming a dimer structure (H3-H4)₂ and this dimer is capped on both sides of the solenoid like structure by a heterodimer of H2A-H2B (Nacheva *et al.*, 1989). In contrast to core histones, the linker histones, like H1, and its isoforms are not components of the nucleosome core, but instead bind to the linker DNA at the nucleosome entry and exit sites, stabilizing the entire complex (Bustin *et al.*, 2005; Kalashnikova *et al.*, 2016). Some examples of structural fragments of dsDNA wrapped around a core of histone proteins – obtained via X-ray diffraction – can be found in the Protein Data Bank (PDB); these include 5DNM, 5VA6, 5B31 (Fig. 1) or 5KGF.

Unless specified otherwise, the word “genome” represents a sequence corresponding to one complete set of autosomes (chromosomes not associated with the sex of the organism) and one of each type of sex chromosome; the result representing both possible sexes. In addition, the “genome sequence” is often a composite read from various individuals. Therefore, the length of a “genome” roughly represents to the length of the haploid cell or gamete (sperm/ovum). The more typical somatic cells of an

Fig. 1 Example of the histone and double stranded DNA (dsDNA) complex (PDB id: 5B31) showing the 1 and 3/4th turn of the dsDNA around the histone core. The coloring scheme for the histone subunits and DNA are as follows: silver blue – H3 (chains A + E), blue – H4 (chains B + F), orange – H2A (chains C + G), yellow – H2B (chains D + H), silver – dsDNA (chain I, J). The Figure is created using Pymol (Delano, 2004; pymol available from <http://www.pymol.org>).

organism contain a fused copy of both the male and female haploid cell DNA. Haploid cells are formed through meiosis (splitting in half the diploid). Somatic cells are replicated through the process of mitosis.

The human genome consists of three billion base pairs (3 Gbp) of dsDNA. The haploid cells have 23 chromosomes and the dsDNA sequence is a monoploid roughly 3 Gbp long. The somatic cells are diploids with 46 chromosomes and a sequence length of approximately 6 Gbp. Naked dsDNA (the dsDNA without the histones) from somatic cells would reach two meters ($2 \text{ [haploid]})(3 \times 10^9 \text{ [bp/haploid]})(0.34 \text{ [nm/bp]})$ if it were stretched out over its full contour length; overstretched (Olson and Zhurkin, 2000), this length would even double. When packaged in the form of chromatin fiber, the overall length is reduced by about one third (Rosa and Zimmer, 2014) where each solenoid shaped nucleosome core is about 6 nm by 11 nm. The distance between each nucleosome is called the *nucleosome repeat length*, (NRL (Routh et al., 2008)). The histone core is extended by H1 linkers. There is nearly always at least one H1 between adjoining nucleosome cores leading to a $n + 1$ rule (Routh et al., 2008). Each H1 linker tends to increase the NRL in increments of 10 bp; coincidentally almost a full 360° turn of the dsDNA helix (Voong et al., 2016; Brogaard et al., 2012). As a result, the NRL ranges from 167 bp (the histone core plus H1 plus one H1 linker, 10 bp; e. g., yeast) to 240 bp (core plus H1 plus an 80 bp linker, echinoderm sperm) (Bascom and Schlick, 2017). The nucleosomes appear to be connected as in an irregular zig-zag (Woodcock et al., 1993; Bednar et al., 1998), which resembles a loose coil formed when “flaking” a rope (Bascom and Schlick, 2017); i.e., rolling out a mountain climbing rope. The globules of dsDNA and histones (the nucleosomes), and the linker(s) form the basic chromatin fiber of somatic cells and gametes.

The H1 linker and other related factors can affect the compactness of the chromatin. For example, the length of the H1 linker appears to influence the organization of the chromatin into an ordered structure. In a study by Routh et al. (2008), chromatin compaction was analyzed when the NRL was either 167 or 197 bp and the linker histone H5 was present or not. The H5 histone is found in chicken erythrocytes and is a variant of the linker histone H1. H5 has a greater binding affinity to DNA than H1, but the influence of H5 on compaction is rather similar. In the absence of H5 (Fig. 2, top two panels), the dsDNA appear to be disordered, especially in the case when NRL was 197 bp. When H5 is present, the structure appears to be ordered. In Fig. 2 (bottom left panel, “+ H5”), when H5 is present and the NRL is equal to 167 bp, the nucleosome appear to form a structure similar to a 20 nm fiber. On the other hand, the 197 bp NRL yields something closer to the 30 nm fiber (Fig. 2, lower right panel).

Depending on the concentration of salt in the buffer, at the length-scale of several nucleosomes and corresponding linkers (NRL approximately 200 bp), there is a tendency for the nucleosomes to become partially ordered. It was long thought that the chromatin beaded up into 30 nm globules (Finch and Klug, 1976); however, such structural regularity has also been challenged (Davie, 1997; Woodcock et al., 1993). Based on observations of small angle x-ray scattering (SAXS) studies on chromatin from HeLa cells, the structure of the chromatin fiber appears to take on a more complex local structure or even possibly random

Fig. 2 The role of the linker histone in determining higher-order chromatin structure for different nucleosome repeat lengths (NRL); 167 bp and 197 bp. (*Upper*) Without the linker histone. (*Lower*) With the linker-histone. To the left of each example, a sample of a simulated structure is shown to provide an impression of the overall arrangement of the nucleosomes. (*Upper*) Here, it can be seen that both the 167 and 197 bp NRL are largely disordered or certainly rather loose in the absence of H5; the 197 case is more so than the 167 case, which is at least wrapped. (*Lower*) Here, it can be seen that both the 167 and 197 bp fibers are quite compact in the presence of H5. (Scale bar: 50 nm.). Reproduced from Routh, A., Sandin, S., Rhodes, D., 2008. Nucleosome repeat length and linker histone stoichiometry determine chromatin fiber structure. *Proc. Natl. Acad. Sci. USA* 105, 8872–8877.

structure (Maeshima *et al.*, 2010; Joti *et al.*, 2012; Nishino *et al.*, 2012; Maeshima *et al.*, 2016). The studies using SAXS to analyze the rough structure of the nuclear material of the HeLa cells revealed a clear 30 nm signal (Joti *et al.*, 2012; Nishino *et al.*, 2012) in the presence of Rpol2. However, after washing away the Rpol2, the peak disappeared. The SAXS data also shows clear 6 nm and 11 nm peaks and a broadband peak for longer length scales (Maeshima *et al.*, 2014) indicating a local lattice-like clustering of 3 or 4 nucleosomes; consistent with a local stacking and tandem arrangement nucleosome units.

The H1 histone protein is particularly sensitive to environmental factors such as ionic strength (Davie, 1997). For example, the existence of 30 nm fibers appears to be partially dependent on the concentration of Mg^{2+} . Later work from Maeshima and coworkers focused more on the salt buffer in the absence of Rpol2 (Maeshima *et al.*, 2016). In Fig. 3(a), the diameter of the HeLa cell nucleus is found to be significantly inflated in the absence of Mg^{2+} (16.4 μm) and becomes increasingly compact with addition of Mg^{2+} (around 8.6 μm , where normal HeLa cell diameters appear to be 7.36 μm (Milo *et al.*, 2010) BNID 104990). In Fig. 3(b), SAXS measurements of nucleosome oligomers (blue) and nuclear material (red) show similar profiles; both show no obvious structure other than a broad peak in the absence of Mg^{2+} and sharper images of 6 and 11 nm peaks at increasing concentrations of Mg^{2+} . In the same study by Maeshima *et al.*, the authors also examined isolated native chicken chromatin fragments that showed similar profiles as the human HeLa cells in Fig. 3(b). Hence, using the chicken linker histone (H5) in Fig. 2 (Routh *et al.*, 2008) instead of human H1 does not change the behavior of chromatin. Finally, Fig. 3(c) shows a proposed progression from a disorder local structure of the nucleosomes in chromatin in the absence of Mg^{2+} , to very compact and possibly disordered structure at higher concentrations of Mg^{2+} . The ion concentrations within the cell of most animals is roughly 140 mM K^+ , 12 mM Na^+ and about 1 mM Mg^{2+} whereas outside the cell it is about 150 mM Na^+ (Auffinger *et al.*, 2011). Therefore, the middle panel in Fig. 3(c) represents the chromatin state closest to the physiological conditions typically found in human cells.

It might be tempting to assume that a regular double helix of dsDNA has almost no influence on the positioning of the nucleosomes on the dsDNA; however, this is not the case. In Todolli *et al.* (2017), it was observed that the bases in the dsDNA sequence can influence the positioning of the histones and consequently the arrangement of the nucleosomes. Presently, there are no first principles prediction methods at the bp level that can explain the arrangement of the nucleosomes (Todolli *et al.*, 2017). If

Fig. 3 Isolated HeLa nuclei showing the effects of Mg^{2+} concentration on the overall chromatin structure (nuclear material). (A) FM images of chromatin structure in the nuclei with 0 (left), 1 (center), and 5 mM Mg^{2+} (right). The insets show the intensity line profiles as measured by scanning (horizontally) between the two yellow arrow heads in each of the images. (B) Sax profiles of nucleosome arrays formed by an oligomer of H1-linked nucleosomes (red) and by HeLa nuclei (red); 0 mM (left), 1 mM (center) and 5 mM Mg^{2+} (right). (C) A schematic of the effects of Mg^{2+} concentration on the characteristic form of chromatin fibers for a 12-mer nucleosomal array. In 0 mM Mg^{2+} , the nucleosomes are highly disordered and separated, in 1–2 mM Mg^{2+} , there is some evidence of regular arrangements of nucleosomes that to some extent generated a 30 nm chromatin fiber structure, though the 30 nm peak is not so visible in the spectrum. With additional increases in Mg^{2+} , the structure collapses into a structure which is largely disordered but compact. Reproduced from Maeshima, K., Rogge, R., Tamura, S., *et al.*, 2016. Nucleosomal arrays self-assemble into supramolecular globular structures lacking 30-nm fibers. *EMBO J.* 35, 1115–1132.

we were able to better understand this local structure, it would be possible to understand the short-range nucleosome-nucleosome (histone coated dsDNA and linker) structure.

It is a well-established fact that histone modifications impact gene expression by altering the overall nucleosome-nucleosome interactions in the chromatin structure through acylation (Davie, 1997), methylation (Kouzarides, 2002; Cheung *et al.*, 2000), phosphorylation (Cheung *et al.*, 2000) and sometimes sumoylation (Shiio and Eisenman, 2003) and ubiquitylation (Nathan *et al.*, 2003). Acylation and deacetylation of the exposed parts of the histone assists in turning transcription on and off (Davie, 1997). It also promotes the recruitment of proteins that can bind diverse parts of the chromatin fiber into loops, which ultimately form transcription factories that become the loci of highly expressed regions through Rpol2 activity (Dunn *et al.*, 2003; He *et al.*, 2008; Jahan *et al.*, 2016; Warns *et al.*, 2016).

A recent molecular dynamics simulation (Zhang *et al.*, 2017) shows that lysine acetylation of the H4 tail with K16Ac yields an increased diversity of conformations and, consequently, the interactions between nearest neighboring nucleosome units. The positively charged side chains of lysine and arginine tend to repel each other in an isolated tail of H4. K16Ac relieves some of this tension and contributes to the folding and stabilization for a variety of conformations of the chromatin. At the same time, since the dsDNA has negatively charged phosphates, there are extensive electrostatic interactions, particularly salt bridges. When the lysine is acetylated, these electrostatic interactions are disrupted yielding a more unstable interaction at the H4 tail and resulting in a more diverse conformation space.

The role of these various histone modifications is quite complex, but the effects appear to strongly influence gene expression and suppression by exposing some parts in unbound regions and burying other parts rendering them largely inaccessible to transcription. In Rychkov *et al.* (2017), Rychkov and coworkers used atomic force microscopy to study various combination of partially assembled nucleosome states: (dsDNA bound to partial histone subunits); hexasome (H2A · H2B) · (H3 · H4)₂, tetrasome (H3 · H4)₂ and disome H3 · H4. The authors argue that the free energy cost of unwrapping the histones is on the order of 40 kcal/mol, which is extremely strong for proteins. Hence, the collective interaction would result in regions of the dsDNA that are protected by the histone octamer subunits and likely to strongly impede the progress of Rpol2 and SA from unwrapping and transcribing and splicing, respectively. Such a large free energy barrier would result in kinetics where unwrapping the nucleosome could consume as much as 10 min of time, yet the unimpeded rate appears to be around 1.4 kbp/s (Shermoe and O'farrell, 1991) and certainly at least a single nucleosome (~200 bp/s) per second (Tims *et al.*, 2011).

To overcome this issue, it has been argued that the histone binding may very well be rather dynamic (Bustin *et al.*, 2005; Bascom and Schlick, 2017) because the histone octamer appear to exist in dynamic equilibrium, regularly binding and unbinding to the dsDNA. This may also result from the partial separation of a much smaller structural unit like a disome (H3 · H4) separating with only a 40 bp sequence being in contact with the positively charged core. In such a case, the structure would only involve some 10 kcal per mole (because the 40 kcal/mol binding is spread over 8 histone proteins). Such a free energy would only require an unwrapping time of a few milliseconds (Rychkov *et al.*, 2017), which is more consistent with the observed speed of transcription of Rpol2 (Shermoe and O'farrell, 1991), though perhaps there are other possibilities.

The details of nucleosome, the interplay of the histones and dsDNA, dynamics of histone modifications such as above mentioned acetylation, other histone modifications, and how these factors influence transcription remain largely unanswered questions. The interplay between these modified histones and the overall structure of chromatin is currently largely unknown (Bascom and Schlick, 2017). How all these variables combine together to determine the distance between the nucleosomes and the local arrangement of nucleosome-nucleosome interactions remains an area extensive research.

Flexibility of Chromatin: Persistence Length/Kuhn Length

In polymer chemistry (Flory, 1953, 1969; Grosberg and Khokhlov, 1994), the stiffness of a polymer is typically expressed in terms of the persistence length (l_p) or the Kuhn length (ξ). The Kuhn length can be thought of as the average length of segments of a chain and persistence length as describing the average curvature of a wire.

In the case of Kuhn length (Kuhn, 1936), one imagines a polymer that is generated as though one were taking equal-distant steps in random directions. For example, Fig. 4(A) shows the mer-to-mer distance (distance between monomers, the red beads) laid on top of a green cord. On top of the green cord, purple beads are shown at a fixed link distance (yellow), which represents the Kuhn length. The overlay of purple beads is sometimes called a freely-jointed polymer chain, and the overall path can be modeled as a Markov chain and approximated using a Gaussian function. The Gaussian function has the property of self-similarity; a feature where at every scale of resolution, the random walk looks the same. Hence, Kuhn length reflects a selected uniform length scale of the random walk; it is often described as beads on a chain, where the "beads" represent the purple dots and the Kuhn length is the distance between the yellow bars in Fig. 4(A). In general, real polymers only reflect this self-similarity at discrete length scales.

The persistence length (l_p) is based on a similar concept known as the worm-like-chain (Flory, 1969) or Kratky-Porod model ((Kratky and Porod, 1949), *op cit.* (Flory, 1969)). In this model, one imagines a long flexible cord like a rope or a rubber hose of length l . Consider two consecutive points along this chain (k and k' , where $k \neq k'$), with each point along the cord represented by its unit vectors $\mathbf{u}_k$ and the angle between $\mathbf{u}_k$ and $\mathbf{u}_{k'}$: $\mathbf{u}_k \cdot \mathbf{u}_{k'} = \cos(\theta_{k,k'})$. It can be shown that the integration with respect to all the angles $\theta_{k,k'}$ would result in $\cos(\theta) = \exp(-l/l_p)$. The l_p (persistence length) expresses the minimum length of a cord that will flex to a curvature of one radian (about 57.3°) without kinking and remembering its original straight position (bending back). In other words, imagine there are two points on the straight polymer with distance d between them. If we can bend the polymer so that the

Fig. 4 Comparison of flexibility in terms of Kuhn length and persistence length. (A) Kuhn length where blue beads represent monomers and purple beads represent the beads. (B) Persistence length where vectors i, i' involve a large bend of angle $\theta_{i,i'}$ and j, j' involve only a small bend of angle $\theta_{j,j'}$. All the angles $\theta_{k,k'}$ are integrated yielding $\langle \mathbf{u}_k \cdot \mathbf{u}_{k'} \rangle = \exp(-n/l_p)$, where $n = l/l_p$ is the persistence length of the polymer chain.

angle between the unit vectors from these points (e.g., $\theta_{i,i'}$ or $\theta_{j,j'}$ in Fig 4B) is 1 radian but after we remove the “bending force” the polymer can return to the straight position, then d is effectively l_p . For example, compare l_p for a rubber hose and a thick steel cable; the thick steel cable cannot bend to 57.3° over the same distance as the rubber hose. How about an iron bar? Given a long enough bar, one will see some visible bending but that flexing may only be obvious on length scales on the order of a football field.

For most real polymers, it is found that the distance between the monomers is shorter than the Kuhn length or persistence length. Hence, both models reflect the tendency of the polymer to behave as though the fundamental structural unit is larger than the size of a single monomer (in most cases).

Moreover, real systems are not completely self-similar at all scales; therefore, there is typically a defined Kuhn length for every polymer. The minimum Kuhn length is typically greater than the distance between the monomers. In the case of *naked* dsDNA (without the histones), this can exceed more than 100 bp, depending on salt concentration (Hagerman, 1988). It can be thought of as a kind of coarse-grained resolution length. In typical polymers, it is treated as a statistical parameter and averaged over the entire structure; however, the value should depend on a variety of factors such as chemical binding interactions, local structural interactions, and other considerations. In RNA, the variability depends strongly on the length of the duplex stem and to some extent single-stranded interactions (Dawson *et al.*, 2013).

In the case of chromatin, the polymer comprises a composite of histone proteins and dsDNA. Because the dsDNA is wrapped around the histone core (Fig. 1), there is a local bending of the dsDNA on the scale of 5–10 bp. Because the wrapping of the dsDNA to the histone core has a binding energy of about 40 kcal/mol (Rychkov *et al.*, 2017), a second Kuhn length exists at the scale of the nucleosome (around 200 bp). Figs. 2 and 3 suggest yet a further hierarchical level; The nucleosomes, (about 10 nm in diameter) appear to aggregate into larger collective structures as a result of their mutual attraction. Therefore, the bead size of the cluster of nucleosomes may not necessarily be precisely 30 nm units (Hansen, 2002; Maeshima *et al.*, 2016); however, at physiological conditions, there is little dispute that there is structure encompassing at least several nucleosomes (Maeshima *et al.*, 2016). The collective interaction of the nucleosomes appears to range from 90 nm (Davie, 1997) (roughly the size of 9 nucleosomes) to possibly 40 nm (about 4 nucleosomes).

Although the length scale is probably better understood in terms of clusters of nucleosomes, the NRL is a variable in the cell; therefore, a single base pair of dsDNA is the most regular and invariant unit to define as the “monomer” and five nucleosomes comprise roughly 1 kbp.

Since the differences in the NRL generate very different patterns in Fig. 1, one should probably surmise that the Kuhn length of chromatin is a variable. Bystricky *et al.* (2004) found an overall persistence length of about 170–220 nm, which corresponds to a Kuhn length of 340–440 nm (comprising 34 to 44 nucleosomes). This latter number seems too excessive but heterochromatin is a highly compact material that may have an effective Kuhn length in this range. The variability might also be explained by various histone modifications including (I) the H1 linker (Bocharova *et al.*, 2012; Bascom and Schlick, 2017), (II) H3 phosphorylation,

(III) H4 K16 acylation (H4K16Ac, (Zhang *et al.*, 2017)), (IV) various expression related CpG islands with their corresponding histone modifications (H4K20me1, H2BK5me1 and H3K79me1/2/3) near the transcription start site, and (V) dynamic histone mobility (Bustin *et al.*, 2005). A reasonable estimate to derive from these considerations is a Kuhn length ranging between 3 and 9 nucleosomes (and possibly up to as many as 22). Further, the difference is partly reflected in whether the region is euchromatin (typically loose) or heterochromatin (typically packed). Thus it must be considered that a truer representation of the chromatin chain is that it has a variable bead-to-bead length (Todolli *et al.*, 2017).

Presently, due to both computational issues and the lack of sufficient resolution of experimental methods, computational models of chromatin typically assume that the chromatin chain is composed of beads of a uniform size ranging between 1 kbp to several Mbp. The distance between beads is, therefore, usually much longer than any Kuhn length associated with either heterochromatin or euchromatin. For the shortest lengths of 1 kbp, there may be consequences to assuming complete plasticity of the chromatin beads if we assume the maximum range of 44 nucleosomes (roughly 8 kbp). However, the SAXS data in Fig. 3 Maeshima *et al.* (2016) suggests that 44 is probably rather extreme. The evidence suggests something akin to 30 nm fibers at physiological salt, possibly ranging between 3 and 6 nucleosomes. Hence, certainly at 5 kbp resolution, chromatin can be treated as a set of uncoupled bead on a chain, and, it would be better to be thinking of corrections for the fact that the true bead size is actually *shorter* than the 5 kbp segments that a computational program would bin the data into. Hence, there is likely to be some loss of information in coarse-graining to such length scales.

It seems arguable that using 5 kbp “beads” represents a range where it is possible to describe chromatin as a Gaussian polymer chain (with a self-avoiding walk correction) and possibly some non-ideal polymer behavior associated with the solvent and buffering characteristics (Flory, 1953, 1969; Grosberg and Khokhlov, 1994; Dawson and Kawai, 2015) of the environment (the nucleus) where the chromatin resides. To this polymer model, one would compute the long-range chromatin interactions mediated by various protein factors (such as CTCF, or Rpol2). Nevertheless, we should be mindful that this uniform length scale homo-polymer Kuhn length is a very rough approximation.

The Role of CTCF Protein and Cohesin in Genome Organization

In addition to the obvious structure of chromosomes during cell division, the chromatin in the interphase state appears to organize into compartments (Munkel *et al.*, 1999; Bystricky *et al.*, 2004). Moreover, on the length scale of a 20 kbp to about 3 Mbp, there appears to be considerable long-range pairwise organization of the chromatin according to both FISH (Guo *et al.*, 2015; Xu and Corces, 2016; Munkel *et al.*, 1999; Bystricky *et al.*, 2004) and any of the chromosome conformation capture (3C) methods particularly ChIA-PET (Guo *et al.*, 2015; Xu and Corces, 2016; Tang *et al.*, 2015) and Hi-C (Dixon *et al.*, 2012; Lieberman-Aiden *et al.*, 2009; Rao *et al.*, 2014). These methods will be discussed in the Subsection titled “Experimental Methods”.

At the level of genetics, there is a plethora of interactions within the chromatin (Ji *et al.*, 2016; Beagan *et al.*, 2016). Several kinds of genetic features that are of special interest here are insulators, enhancers and promoters. The genetic boundary elements, known as insulators, have the ability to effectively block the interaction between enhancers and promoters. The promoters mark the region of the dsDNA sequence that attracts proteins that initiate transcription and are typically located near the transcription start sites (upstream on the sense strand). Enhancers are relatively short fragments of dsDNA where transcription factors can bind to increase the likelihood of transcription of a particular gene. Enhancers amplify the transcription rate of a specified gene (Sapojnikova *et al.*, 2009). Unlike promoters, enhancers can be located far away from the transcription start site on the dsDNA chain (Fraser *et al.*, 2015).

The CTCF protein factor has long been associated with insulators (Lewis and Murrell, 2004; Dunn *et al.*, 2003), tending to mark the boundaries between salt soluble regions (often expressed) and insoluble regions (rarely expressed) (Jahan *et al.*, 2016). The CTCF protein is an 11 zinc-fingers protein that binds CCCTC motifs (Ji *et al.*, 2016; Tang *et al.*, 2015; West *et al.*, 2002; Rao *et al.*, 2014). The binding of CTCF involves at least 4 of the 11 zinc-fingers and is to specific sequences (Renda *et al.*, 2007). It is generally thought that two CTCFs form a homodimer that can cause two distal regions of DNA to form into a loop (Ji *et al.*, 2016); though a recently published article describing the structure of CTCF bound to dsDNA noted that no dimerization was observed (Yin *et al.*, 2017). By creating a loop mediated by CTCF proteins, the promoter(s) and enhancers of a given gene, and distant associated parts of the gene on the DNA sequence, are brought in close spatial proximity (Doyle *et al.*, 2014). The CTCF binding sites also correlate with alternative splicing (Warns *et al.*, 2016) and differentially methylated domains (Lewis and Murrell, 2004).

Cohesin is also a key factor in the formation of many CTCF contacts. Cohesin is a large complex of proteins and is closely associated with the formation of the chromosomes during mitosis and meiosis and plays a general role in chromatin stability (Hirano, 2015; Nasmyth and Haering, 2009; Kudo *et al.*, 2009; Ohta *et al.*, 2011). However, cohesin also appears to play an important role in the binding of some CTCF homodimers (Ji *et al.*, 2016; Nasmyth and Haering, 2009; De Wit *et al.*, 2015; Tang *et al.*, 2015; Tark-Dame *et al.*, 2014; Downen *et al.*, 2014). The chromatin loops are often closed by a pair of CTCF proteins that preferentially adopt a parallel orientation where the CTCF binding partners point into the loop (De Wit *et al.*, 2015; Tang *et al.*, 2015; Szalaj *et al.*, 2016; Guo *et al.*, 2015) as shown schematically in Fig. 5(A). There are some indications that the CTCF tends to bend the chromatin at its binding position (Macpherson and Sadowski, 2010). Since the dimer was not observed (Yin *et al.*, 2017), dimer formation may require the presence of cohesin and possibly other factors. When the CTCF partners are pointing away from the loop in divergent loops (Fig. 5(B)), the binding is far weaker, and likewise, tandem loops (Fig. 5(C) and (D)) appear to have an intermediate frequency of occurrence (Tang *et al.*, 2015). It is currently not clear whether divergent and tandem loops also involve

Fig. 5 Examples of various types of loops formed by CTCF dimerization (combined in some cases with cohesin) and its interactions with chromatin. (A) A convergent loop, (B) a divergent loop, (C) a tandem right loop, (D) a tandem left loop, and (E) CTCF islands composed of loops from A and, in the top left hand region of the loop, a singleton is also indicated. The 5' to 3' direction of the sense strand of the DNA sequence is indicated by the red arrows, cohesin is indicated by the blue bar that closes one end of the CTCF, and the implied sequence direction for the CTCF motifs are indicated by the pointed-end of the CTCF objects.

cohesin. Models for the interplay of CTCF and cohesin will be discussed in the last section of this review (particularly in the subsection on loop extrusion).

Multiple loops can co-localize within the same three dimensional genomic loci; the process is mediated by many CTCF dimers that form together into CTCF islands, or rafts (see Fig. 5(E)). Such proximate collections of loops are defined here as chromatin contact domains (CCDs), similar to the term topologically associating domains (TADs), which is used widely in the field of 3D genomics. Such CCDs lengths often range between several kbp to several Mbp and show considerable similarity between cells and/or stages of cell development (Dekker and Mirny, 2016; Beagan *et al.*, 2016; Ji *et al.*, 2016; Tang *et al.*, 2015; Rao *et al.*, 2014). To a lesser extent, Rpol2 also influences large regions of chromatin structure (Dunn *et al.*, 2003; He *et al.*, 2008; Jahan *et al.*, 2016; Warns *et al.*, 2016).

On the global scale of chromatin associated with this histone-dsDNA complex, the overall topology of the chromatin appears to regulate gene expression by delineating regions of transcription where active and repressed chromatin can be found because distant parts of the chromatin chain are brought into proximity of each other in loops (Ji *et al.*, 2016; Ulianov *et al.*, 2016; Tang *et al.*, 2015; Beagan *et al.*, 2016; Dekker and Mirny, 2016; Buenrostro *et al.*, 2015; Rao *et al.*, 2014). Chromosomal rearrangements and changes in the shape of the cell are also strongly correlated with malignant cells (He *et al.*, 2008; Davie, 1997; Schuster-Bockler and Lehner, 2012) suggesting that some cancers occur when normal patterns of CTCF binding begin to break down. The interplay of cohesin with enhancers, repressors, insulators and promoters and various histone modifications is very intricate (Merkenschlager and Odom, 2013) and beyond the scope of this work. Beside CTCF and cohesin, several other proteins are postulated to be involved in forming chromatin loops. They include Rpol2 mediator, Yin Yang 1 (YY1) and BORIS (Pugacheva *et al.*, 2015; Weintraub *et al.*, 2017; Kagey *et al.*, 2010).

It remains unclear how the nucleosomes are unwound and transcribed into pre-mRNA and processed by the spliceosome to produce mRNA. Moreover, although the nucleosome loci affect the type of exon/intron splicing that occurs (Warns *et al.*, 2016; Voong *et al.*, 2016; Shukla *et al.*, 2011), the details of the mechanism are still unclear. There appear to be promoter-proximal nucleosomes, where some of the positively charged nucleosome contributes to the pausing of Rpol2 (Voong *et al.*, 2016; Shukla *et al.*, 2011). How these processes are carried out remains an area of intense research.

Methods for Evaluating Chromatin Interactions

In this section, we consider both the essential experimental and computational techniques that are used to study chromatin interactions and structure. We start by reminding the reader that the field of biology is very complex and demands considerable openness to multidisciplinary approaches to interpret and understand what we observe. For example, many research papers in the field have been written by people unaware of many decades of research in polymer physics. Likewise, as we forge ahead in new

Fig. 6 Comparison of the mass of the DNA (directly proportional to the length of the sequence) with respect to the volume of the cell nucleus for plant species. (Taken from government document Nauman, A.F. 1979. Plant Nuclear Data Handbook: Radiosensitivity in Plants. Available at: <https://www.osti.gov/scitech/servlets/purl/5369196>, public domain).

techniques and are faced with the explosive sea of literature, we often think that work 50 years ago is irrelevant today. For example, in the early '60s in a somewhat obscure study (Baetcke *et al.*, 1967), it was discovered that the volume of the cell depends linearly on the length of the genome or the number of base pairs (bp) of the chromatin. Moreover, a correlation between cell volume and nuclear volume has been known since the late 19th century (explained in Gregory (2005)). Hence, to some extent, once again, we have reinvented the wheel – we should have expected this result, not been surprised by it. The important thing, however, is not just “what” but “why” we observe certain features of chromatin and recent developments in the field have helped us understand more of the “why” question and are an exciting area of new discoveries.

Experimental Methods

This section summarizes some of the most commonly used experimental techniques in studying chromatin and partly reviews some of the history. The optical techniques of fluorescence in situ hybridization (FISH) have forged ahead on discovering 3D compartment in the nucleus (Fraser *et al.*, 2015). Recently developed techniques like chromatin conformation capture (3C) and derivative technologies such as Hi-C (Rao *et al.*, 2014) and ChIA-PET (Li *et al.*, 2017) allow us to propose 2D maps of the interacting parts of chromatin. These method allow us not only to see which parts of the genome are in spatial proximity but also, in case of ChIA-PET, which proteins are responsible for maintaining the genome stability. This invaluable knowledge relies heavily on being able to propose a 3D structure of the chromatin using computational techniques. Beside the short introduction to the abovementioned methods we briefly discuss of their strengths and weaknesses.

Size of the Cell Nucleus Correlates with Chromatin Chain Length

Since the early '50s, numerous studies have shown that there is a strong correlation between the quantity of DNA in a given cell and the size of its nucleus in both the animal and plant kingdoms (Baetcke *et al.*, 1967; Price *et al.*, 1973; Gregory, 2017, 2005; Jovtchev *et al.*, 2006; Beaulieu *et al.*, 2008; Nauman, 1979). To obtain the size of the genome, most of these studies measured the mass (C-value) of the DNA (in pg). Very similar conclusions were even reached in the 19th century when the volume of a given cell was compared with the volume of its nucleus (*op. cit.*, (Gregory, 2005)). Likewise, DNA content and chromosome volume (Baetcke *et al.*, 1967) correlate. This phenomenon is also observed throughout the plant and animal kingdoms (Hodgson *et al.*, 2010; Mirsky and Ris, 1951; Beaulieu *et al.*, 2008). Furthermore, when the size of the nucleus deviates from this tendency, it is usually an indication of diseases like cancer (Webster *et al.*, 2009). In Fig. 6 we show the correlation between nuclear volume and C-value (the mass of the DNA) from Nauman (1979) for various plant species. Fig. 7(A) shows a similar fit for animal species reproduced from

Fig. 7 Similar examples to Fig. 6 (A) A reproduction of the data from Baetcke *et al.* (1967). (B) A comparison of the quantity of nuclear DNA (measured in base pairs) with respect to average diameter of the nucleus for measured species of fish (the red dot in the figure indicates the position of the human genome and is included for reference and comparison). From data obtained from the Animal Genome Size Database. Reproduced from Gregory, T.R., 2017. Animal genome size database: Cell size dataBase. In: Gregory, T.R. (Ed.). Available at: <http://www.genomesize.com/cellsizes/>. Fig. 7(B) is plotted with linear axes for easier readability, plotted log-log, it looks similar to 5A.

Baetcke *et al.* (1967) and Fig. 7(B) shows a fit of C-values with respect to the average nuclear diameter for available information on ichthyic genomes (from Gregory (2017)) and the human genome for reference and comparison (the red dot). Whereas there is some scatter, the conclusions from the abovementioned articles are quite reproducible.

To understand and appreciate the significance of this behavior, we need to delve into some of the essential mathematical formulas. In the traditional model of an ideal polymer (Flory, 1953; Grosberg and Khokhlov, 1994), the distance between the ends of the polymer chain (r , also known as the end-to-end distance) can be shown to be a function of the square root of the number of monomers (N); $r \propto N^{1/2}$. This is the general property of the random walk (Flory, 1953; Grosberg and Khokhlov, 1994) and is known as the Gaussian polymer chain (gpc) model. The formal definition is given with Eq. (1):

$$r = b\sqrt{\xi N} \quad (1)$$

where b is the distance between adjacent monomers on the polymer chain, ξ is the Kuhn length (Kuhn, 1936) – a measure of the stiffness of the polymer – and r is measured in units monomer-monomer separation distance b . It must be noted that, in the literature, the parameter b often incorporates the Kuhn length. Thus in some cases, b would be equivalent to ξb in Eq. (1); $b \Rightarrow \xi b$.

This *ideal polymer* relationship often requires additional modification to Eq. (1) because real polymers can end up in good solvent (e.g., polystyrene in hexane) where the polymer tends to soak up the surrounding solvent and consequently swell in size. Likewise, a polymer can end up in poor solvent (e.g., polyvinylchloride in water) and become very compact because the monomers in the polymer tend to exclude solvent in favor of its own residues. This behavior is known as the excluded volume and it affects the value of the exponent in Eq. (1), which is often labeled ν ;

$$r = \xi^{1-\nu} N^\nu b \quad (2)$$

Thus for the ideal polymer where $\nu = 0.5$, we obtain a formula identical to Eq. (1); $r = (\xi N)^{0.5} b$. For non-ideal polymer ν can range from $1/3 < \nu < 2/3$.

Examining Figs. 6 and 7 in terms of volume relationships it can be seen that the typical volume of the nucleus (V_{nuc}) grows essentially linearly with genomic content: $V_{nuc} \approx \rho N$, where ρ is a proportionality constant. In Fig. 7(A), the exponent is close to 1 (when fitted to volume) and in Fig. 7(B) (when fitted to diameter) the exponent is close to 3. Although there is some scatter, the weight of the measured data suggests a strong tendency toward $V_{nuc} \propto r_{nuc}^3 \propto N$. If we use the formula for radius from Eq. (1) (i.e., $r_{nuc} = b\sqrt{\xi N}/2$) to calculate the volume of an ideal sphere we get $V_p = (4\pi/3)(r/2)^3 = (\pi b^3/6)(\xi N)^{3/2}$. We can see that the volume of an ideal polymer (V_p) should thus grow as $V_p \sim N^{3/2}$. The ratio of V_p and V_{nuc} is given in Eq. (3).

$$\frac{V_p}{V_{nuc}} \approx \frac{(\pi/6)(\xi N b^2)^{3/2}}{\rho N} = \frac{\pi \xi^{3/2} b^3 N^{1/2}}{6\rho} \propto N^{1/2} \quad (3)$$

Thus it can be clearly seen that chromatin in the nucleus must be far more compact than what can be expected for an ideal polymer. Since the size of a genome can range from 10^4 (for viruses) all the way to more than 10^{10} (for some species of plants and some animals, particularly amphibians), this compacted structure is probably essential for optimal functioning of any cell and some specific mechanism must exist that allows chromatin to remain so condensed.

In eukaryotic cells, the nucleus provides confinement for the chromatin chain. When a polymer is inserted into a capillary where the inner radius of the capillary (r_{cap}) is smaller than the size of the ideal polymer (r_p from Eq. (1); i.e., $r_{cap} < r_p$), the maximum radius of the polymer vertical to the axis of the capillary approaches the inner radius of the capillary and the polymer balls up into as many globules as required to pack the polymer into the capillary; a process known as reptation (Grosberg and Khokhlov, 1994; Thirumalai and Shi, 2017).

One might therefore imagine the chromatin fiber to behave as an ideal polymer chain embedded in a capillary, to some extent. To preserve $V_{nuc} \propto N$, one might assume that $\nu \sim 1/3$. However, the environment of the cell is not particularly ideal for DNA with its somewhat hydrophobic bases; however, its sugars are quite hydrophilic and the cellular environment is a vast heterogeneous mixture of many proteins, small molecules, water, ions and DNA/RNA. Hence, it would be better to imagine that the heterogeneous properties of the nucleus (without other considerations) should correspond to V_p , an ideal polymer, in the "polymer melt" consisting of all the different components of the cell's nucleus. Nevertheless, $\nu \sim 1/3$ would explain how a nuclear membrane could compress a range of genome sizes from 10 Mbp to 10 Gbp; i.e., it doesn't have to.

More recently, independent of the above findings, a linear relationship between nucleus volume and the amount of DNA ($V \propto N$) was observed with the first high throughput sequencing experiment using the Hi-C strategy (Lieberman-Aiden *et al.*, 2009). In that study, it was noticed that the likelihood of observing contact positions was inversely proportional to the genomic distance s between the contact points (wherein the number of contacts vanished as $1/s$ rather than $1/s^{3/2}$ (what would be expected if the chromatin behaved like an ideal polymer). The measuring of contact frequency is obviously different from the volume but whether the contacts had been random or specific; their frequency should correlate with the end-to-end distance, for a given genomic distance s . The frequency of observed contacts in any polymer should drop off as $1/s^\alpha$, where α is a constant. In the work of Lieberman-Aiden and co-workers, they proposed a fractal globule to explain this discrepancy from the behavior expected for an ideal polymer.

This again prompts the proposal that the chromatin is essentially a polymer in poor solvent and, therefore, $\nu \approx 1/3$; even though it is a heterogeneous polymer melt of diverse materials. However, studies of various models of chromatin tend to disagree with the simplistic collapsed polymer model (Rosa and Zimmer, 2014; Jerabek and Heermann, 2014). What has been discovered over the years, particularly from fluorescence in situ hybridization (FISH) experiments (Wang *et al.*, 2015; Brackley *et al.*, 2016; Giorgetti *et al.*, 2014; Bickmore and Van Steensel, 2013) and more recently experiments using Hi-C (Thurman *et al.*, 2012; Lieberman-Aiden *et al.*, 2009; Rao *et al.*, 2014; Ulianov *et al.*, 2016; Jin *et al.*, 2013; Dixon *et al.*, 2012) and ChIA-PET (Fullwood and Ruan, 2009; Tang *et al.*, 2015; Szalaj *et al.*, 2016; Li *et al.*, 2017; Ji *et al.*, 2016; Downen *et al.*, 2014) strongly suggest that the genome in the cell is highly organized and different segments of the genome are compartmentalized for protein expression and maintenance. The main counter argument about organization of the genome has been that the diffusion rates for various factors could also be roughly 10^{-6} s; hence, the promotor is just generated in large enough quantities that it can diffuse to the desired gene in reasonable time. The rates are arguably fast enough. However, it suggests that a lot of factors are generated (indeed, wasted) and the cell machinery must remove these factors. With the introduction of CTCF binding and cohesin, this argument has become increasingly moot in recent years.

In terms of structure, there is nothing in the theory of a collapsed polymer (Grosberg and Khokhlov, 1994; Mckenzie, 1976) stating that the agents associated with this collapse simply cannot be the result of protein factors located at specific locations on the dsDNA chain (such as the CTCF and cohesin, discussed in the previous section). What the theory assumes is that there are mutual weak binding interactions between the residues of the polymer. In a simple collapsed polymer model, only random contacts are observed and the dynamics of the polymer chain would quickly lead to knots. (As pointed out in the Introduction, an earphone dropped in a bag quickly knots.) This is because there are just so many degrees of freedom in a flexible cord (Mckenzie, 1976). Because the cause of the globular structure is uniform attractive self-interaction forces between the polymer itself (Mckenzie, 1976), the enormous number of degrees of freedom mean that even if the contacts have a definite organization, natural selection pressures will have forced that organization to adopt a structure around the minimum free energy that resembles one of the many random configurations that could be generated with the same free energy for a set of heterogeneous contacts. Hence, whereas in principle v represents a globular structure with uniform attractive contacts, the overall size of the organized structure with heterogeneous contacts can also follow an $r^3 \propto N$ rule. The nuclear envelope is reflecting just exactly the size of the nuclear material, the chromatin fiber. Hence, although more organized than a traditional globular structure (Grosberg and Khokhlov, 1994; Flory, 1953), the overall distribution of the contacts still resembles a collapsed polymer.

Optical Approach: FISH

Before the advent of high-throughput sequencing techniques that can directly quantify proximity ligation products in contact libraries, the commonly used method for determining nuclear organization and chromatin conformations was fluorescence in situ hybridization (FISH).

This optical technique was first developed in the '80s (Langer-Safer *et al.*, 1982) and has been used from the beginning for various cytogenetic studies. In the earliest stages, it was used to identify the presence or absence of certain DNA sequences and therefore effectively to map the location of various genes on the chromosomes. This was done by attaching a probe that carried a fluorophore to a sequence of DNA using in situ hybridization and next observing the specific part of DNA to which probed attached using fluorescence (O'Connor, 2008). Fluorescence microscopy can be used to track gene expression with probes binding to mRNA and be used to identify the relative distance between two positions on the chromosome, producing a 2D map. It can also be used to identify the overall structure of a region of the nucleus and it can be used to model dynamics.

FISH is a cytogenetic approach; i.e., a study of genetics in terms of the structure and function of the chromosomes, the structure, architecture and function of the genome. Since the observed information comes in the form of visible light (about 900 to 400 nm), this limits the direct resolution to the scale of tenths of micrometers in the best case (less than 200 nm in the xy -plane and less than 500 nm along z -axis (optical axis)). However, with knowledge of the DNA sequence and targeted placement of the fluorescence probes in the genome sequence the method permits to infer that distant regions on the linear sequence are in proximity of each other. We will not discuss super-resolution microscopy or EM microscopy, which are also rapidly advancing.

Specific examples of the interaction between the cohesin complex and the CTCFs at the level of x-ray crystallography have yet to be obtained. Therefore, we can only infer the interactions between these components by their regular association. What is more typically done is to use FISH to tag different loci of the chromatin and in this way the dynamic association of diverse parts of the chromatin chain in live cells can be visualized (Chuang *et al.*, 2006; Tumber and Belmont, 2001; Chubb *et al.*, 2002; Muller *et al.*, 2010). In such studies, it has been shown that the arrangement of the chromosomes can change from a largely peripheral location to a more internal region of the nucleus and that there is considerable compartmentalization in the architectural arrangement of the chromosomes within the nucleus; at least that there is a clear tendency for various sectors of the chromatin to appear in a similar distribution from cell to cell, though dependent upon the particular phase of the cell. It would seem reasonable that an efficient way to use the transcription production machinery is to place it in various central locations and bring the diverse parts of the chromatin to those loci rather than move the very complex spliceosomal machinery with a plethora of moving parts to specific locations in the cell. Efficient, shared usage of common but complex factory resources is used in designing assembly lines.

FISH Methods: Experimental Considerations

Whereas the broad 3D features of chromatin can be deduced by FISH experiments, to set up an experiments that identify the interactions within the chromatin on the length scales that might be considered to influence expression and transcription requires an ingenious choice of the right markers on the right genes. Only then FISH can be used to directly infer the loci between two locations in the genome and other information. One can imagine that this is very much a trial and error approach. It should be clear that this process of identifying these interactions requires considerable labor, and one is still largely limited to a resolution of maybe 0.5 μm . In the end, one will need to employ a wealth of computational tools to interpret the observed data. A different way to approach the interactions of chromatin is to map what areas of the chromatin are in contact with each other; i.e., showing the interactions between diverse parts of the chromatin chain. The number of instances of a given contact in a very large collection of the same type of cell in a similar phase of the cells is a measure of how likely a given interaction occurs. Once a 2D map is constructed, it is possible to infer the local 3D structure of the chromatin – or more correctly, the ensemble of structures that comprise the chromatin in the given region of the cell. At some point, the larger picture of the whole cell has too many degrees of freedom to be modeled solely with a mere contact map, but in terms of the many compartments within the cell nucleus, these length scales border closer to the minimum resolution of the 3D FISH experiments.

3C Methods

There are several experimental contact mapping techniques (Hakim and Misteli, 2012) based largely on the “chromosome conformation capture” (3C), which was developed by Dekker *et al.* (2002). The essence of the concept is that a population of cells is chemically fixed with formaldehyde. The formaldehyde forms cross-links between neighboring parts of the chromatin in the form of covalent bonds (Dekker *et al.*, 2002; Jackson, 1999; Orlando *et al.*, 1997). Restriction enzymes are used in the next step to digest the chromatin leaving small fragments that represent the parts of the chromatin that were in proximity of each other. After diluting the DNA, ligase is employed to link pairwise fragments (also sometimes called anchors) that are then amplified with PCR (Dekker *et al.*, 2002; Abou El Hassan and Bremner, 2009; Hagege *et al.*, 2007) and finally sequenced. During analysis, the sequences at similar locations of the genome are clustered according to the resolution; roughly on the order of the square of the number of cells analyzed. This basic protocol was often modified to improve the signal-to-noise ratio or to limit the contacts to ones resulting from mutual interactions of specific protein factors (like CTCF or Rpol2).

The term “anchor” is used to refer both to a uniquely identifiable sequence of DNA (Mckernan *et al.*, 2009) and to a pair of uniquely identifiable sequences that interact with each other in the form of loops (Fullwood and Ruan, 2009). The term “intra-ligated” indicates contacts (cross-links) that result from the coincidental interactions of the chromatin or local bending and compaction of the chromatin. Such interactions are not likely to serve any significant physiological purpose in terms of gene expression or regulation. Inter-ligated contacts are ones that result from long-distance interactions mediated by, for example, CTCFs and cohesin.

The chromosome conformation capture-on-chip (4C) technique was designed to help speed up the throughput and as a consequence to increase the resolution of the 3C (Lomvardas *et al.*, 2006; Simonis *et al.*, 2006; Wurtele and Chartrand, 2006; Zhao *et al.*, 2006). As with 3C, the interactions are cross-linked and selected restriction enzymes are used to digest the chromatin away from the contacts of interest. The method relies on generating circular ligation products between a selected fragment and the rest of the genome. The circular products are quantified using microarrays or sequencing. The advantage is that one can deduce all the interactions between a given, specified location and the rest of the genome. The chromosome conformation capture carbon copy (5C) is an extension of 3C in that, rather than the ligation products from specific restriction fragments (like 4C), all the restriction fragments are used and amplified in a microarray. The “carbon copy” is because it essentially amplifies the 3C data. The advantage is that rather than detecting the interactions of a specific fragment, it measures the relative proportions of the amplified product.

Hi-C Methods

The Hi-C method is a high resolution genomic approach that can capture chromatin loops, domains (in this case called topologically associated domains TADs), and many local features related to unspecific long-range protein-mediated chromatin interactions. The TADs have borders strongly enriched with the CTCF binding sites (Nichols and Corces, 2015; Alipour and Marko, 2012) and their sizes are typically found over length scales of 1 to 3 Mbps.

The Hi-C method essentially adds high-throughput sequencing to help build libraries that quantify the proximity ligation products. The method is able to cover the entire genome at a certain size resolution. Like 3C, the population of cells are fixed with formaldehyde and digested with different types of restriction enzymes. At this stage, the overhangs in the restriction fragments

Fig. 8 Example of ChIA-PET data of the X chromosome from 150882227 to 153764804 in human lymphoblastoid cells (GM12878).

are filled with Klenow enzyme and various deoxynucleoside triphosphates (dNTPs) including biotin-14-dCTP and the products ligated and purified. The libraries are sonicated and subjected to pulldown with streptavidin-coated beads.

ChIA-PET Methods

The “chromatin interaction analysis by paired-end tag sequencing” (ChIA-PET) is an extension of Hi-C in the sense that ChIA-PET selects for ligation products of interactions of specific proteins; typically Rpo12 or CTCF (Fullwood *et al.*, 2009a; Handoko *et al.*, 2011; Tang *et al.*, 2015; Sandhu *et al.*, 2012). The paired-end tag sequence (PET) refers to a short DNA sequence that is unique enough to identify a particular segment of the genome, a sequence at least 13 bp long (Fullwood *et al.*, 2009b). Rather than applying restriction enzymes, chromatin fragments are created by sonicating the cells and selection for specific proteins is achieved by applying chromatin immunoprecipitation (ChIP); specifically targeting proteins like CTCF that are bound to the chromatin and retained in the cross-linked fragments. To the ends of the co-immunoprecipitated DNA segments, biotinylated DNA linkers are added and the DNA fragments are ligated together. This is the paired end tag (PET). Purification is carried out using streptavidin beads and paired-end sequencing. The ChIA-PET experiments yield pair-end-tag (PET) data; ligation products of different parts of the chromatin chain. Each half of the ChIA-PET products is next mapped to the reference genome. An example of this method for a part of the X chromosome from 150,882,227 to 153,764,804 from human lymphoblastoid cells (GM12878) is shown in Fig. 8.

Results of ChIA-PET/Hi-C Methods

There are several important observations to consider that result from these genome mapping experiments. First, we compare the general outcomes of 3DFISH and the more recent ligation products. Second, we examine some of the larger differences found in the ligation techniques.

3DFISH vs Ligation Products of ChIA-PET and Hi-C Methods

The ligation products of both Hi-C and ChIA-PET experiments yield both intra-ligated and inter-ligated products. With Hi-C data, any contact can be either intra-ligation or inter-ligated, irrespective of whether the interactions involve CTCF or other target proteins. On the other hand, for ChIA-PET data, the intra-ligation is limited to a range of about 8 kbp and the remaining data can all be treated as inter-ligation pairs of sequence fragments (Szalaj *et al.*, 2016). This distinction can be made because ChIA-PET data involves the targeting of ChIP products: the CTCF proteins located at chromatin binding sites or other well defined markers such as proteins associated with Rpo12. Since there is a significant hyper-exponential shift in the number of counts for data less than 8 kbp and the highly flexible chromatin chain is likely to cross within this range, the majority of contributions within 8 kbp clearly must be coming from self-ligated products. On the other hand, beyond this 8 kbp range, the behavior is quite different. The paired end tag (PET) counts or anchors can show a drastic increase in counts at specific locations on the chromatin chain. This is certainly characteristic of the expected behavior of CTCF protein-protein binding sites and similar observations are obtained from Rpo12 sites (a collection of protein subunits) using ChIA-PET. Therefore, whereas we cannot completely rule out the possibility of some small fraction of self-ligated products within the data beyond 8 kbp, such contributions are certainly small and cannot contribute significantly to the statistical weight even if given they are present.

After filtering, both Hi-C data and the singleton ChIA-PET data appear to be rather similar overall, characterized by high Pearson correlation coefficient between both heatmaps (Tang *et al.*, 2015; Szalaj *et al.*, 2016). With Hi-C, there is a mixture of ligation between diverse parts of the chromatin chain and self-ligation interactions. Therefore it is more difficult to untangle self-ligation for Hi-C data compared to ChIA-PET data.

Although the positions of the CTCF dimers is accurate to roughly the length scale of the nucleosome (roughly between 150 and 200 bps), practical considerations currently set limits on the amount of statistics that can be acquired; e.g., limits on data acquisition, storage, and processing, and limits due to time and budget constraints. Currently, these limits are perhaps on the order of 1 kbp (Tang *et al.*, 2015; Rao *et al.*, 2014) – at least five times larger than the approximate size of a nucleosome.

There remain some questions about the differences of FISH and the various 3C methods. One important issue is coverage. It remains unclear if the cross-links created during fixing the cells are uniform throughout the chromatin sample or if they favor the boundaries of the nucleus; for example (Gavrilov *et al.*, 2013; Ulianov *et al.*, 2016). So specificity and stability may be issues.

Important Considerations of Ligation 2D Mapping

A major limiting factor in ChIA-PET and Hi-C measurements is statistics. As a practical example, there are some 30 million nucleosomes (nuc) in the human genome ($2 \times 3 \times 10^9$ [bp]/200 [bp/nuc]). In a recent ChIA-PET measurement (Tang *et al.*, 2015), roughly 30.8 million reads were obtained from roughly 100 million human lymphoblastoid cells (GM12878). Hence, there would be roughly 1 count per nucleosome (on average). However, if the data is binned into 5 kbp segments (about 25 nucleosomes per bead: 5000 [bp]/200 [bp/nuc]), then this leads to an average coverage of about 25 counts per bin. For ChIA-PET data exceeding the 8 kbp boundary, the CTCF or Rpo12 only yield inter-ligated products. In other words, the short range intra-ligated contacts that generally result from local chromatin looping, would be discarded, and the random long-distance spurious intra-ligated contacts are eliminated because ChIA-PET, as already mentioned, selects only specific interactions such as CTCF and Rpo12. Clearly, single counts in this type of measurement can be spurious. This is the advantage of a thermodynamic model involving statistical weights; the most significant interaction show up constantly and the weak interactions contribute minimally to the overall structure.

With these considerations, for typical sampling of some 100 M reads, it is probably more instructive to focus on 5 kbp resolution data (5 kbp beads) because it represented the best compromise between obtaining sufficient details of the CTCF

binding sites without rarefying the intensity of individual pair contacts in the heat maps to such an extent as to render the noise from potential spurious contacts excessive. In terms of the polymer behavior of the chromatin, a 5 kbp resolution means that each 5 kbp genomic segment is represented as single bead. At this length scale, the detailed conformations of the individual nucleosomes (~ 200 bp) and mutual interactions within each segment are blurred out rendering a segment that can be treated as though it had the flexibility of a single bead on a string in the polymer chain model. Finally, a 5 kbp resolution permits detection of interligation products just at the boundary of the 8 kbp window. Unlike the data in a range less than 8 kbp, the number of PET counts (from 31 M reads) appears to be less than four for nearest interactions at 5 kbp resolution but anchors describing very distant contact points can possess hundreds of PET counts.

Measured in terms of the genomic distance (s) between bead i and bead j (for $j > i$), where $s = (j - i + 1)$, the likelihood of finding contact points on the chromatin chain between bead i and bead j (the contact probability) for Hi-C and ChIA-PET data tends to decrease as a function of the inverse of the genomic distance

$$p_c(s) \propto s^{-\alpha} \quad (4)$$

where α is a dimensionless scaling parameter. This is also known as the pair interaction frequency (PIF).

Presently, it appears that estimates of α have varied drastically (Barbieri *et al.*, 2013a,b; Chiariello *et al.*, 2014) depending on the organism (e.g., drosophila, 0.7 for active regions and 0.85 for inactive; yeast, 1.5), cell type (e.g., human embryonic stem cells, 1.6, interphase lymphoblast cell, 1.1, and metaphase HeLa cells, 0.5), and theoretical models (e.g., (Meluzzi and Arya, 2013) indicates that unrestrained fits yielded 2.23, and restrained fits 3–8). These values for the α -parameter are estimated using Hi-C data. In the latter examples, the large values for α may reflect the harmonic potential that was used. Nevertheless, predictions of $p(s)$ are not simple in general. If we presume the polymer characteristics of the chromatin as discussed in the previous section, then α should be assumed to be around 1/3 if measured in one dimension, and 1 if the probability is measured in volume. Since s (Lieberman-Aiden *et al.*) is specifically genomic distance (the number of base pairs or the linear distance covered by said base pairs), this is probably a source of confusion in the literature.

Computational Models of the Mechanism

There are a variety of computational models that have emerged in recent years based on polymer science methods that try to explain the behavior of chromatin and satisfy the volume probability measure of $\alpha = 1$. A comprehensive review of all the approaches is beyond the scope of this work. Here, we will focus on two such models that have become most popular in recent years: the loop extrusion model and the strings and binders model. We will not discuss molecular dynamics and Monte Carlo simulation techniques – such as the random walk giant-loop model, Multi-loop subcompartment (MLS) model (Munkel *et al.*, 1999), Entropy-driven chromosome organization (Rosa *et al.*, 2010) and many, many others – because these topics are covered in detail in a recent review (Rosa and Zimmer, 2014) and follow the general concepts of polymers outlined above.

Fig. 9 The loop extrusion (LE) model. In this model, the loop extrusion factor (F) binds to the polymer chain in A, and progressively ratchets along the polymer chain one unit at a time (perhaps nucleosome by nucleosome) gradually creating a larger loop (B, C, D and E). Eventually, the loop cannot grow any larger because the loop extrusion factor collides with a boundary element (labeled BE) or it runs into an additional loop extrusion factor as shown in E.

Loop Extrusion Model

The loop extrusion (LE) model is an example how to understand the process of loop formation in chromatin features. The model was introduced with the notion that it behaves conceptually like the long-distance intracellular delivery systems like kinesin and dynein motor proteins that transport their cargoes along microtubule tracks (Hirokawa and Takemura, 2005; Vallee *et al.*, 2004).

The LE model was originally proposed in Marko and coworkers (Alipour and Marko, 2012) and further developed by Mirny and coworkers (Dekker and Mirny, 2016; Fudenberg *et al.*, 2016) and is depicted in Fig. 9. The chromatin is represented as a polymer consisting of beads separated by some specific distance; e.g., 1 kbp, 5 kbp, etc. Initially, loop extruding factors (LEF) – probably cohesin – binds to a region on the chromatin comprising neighboring beads or, possibly, a small loop formed by a few beads. Although the role of LEF was not assigned to any particular protein, it is now widely accepted that this role is realized by cohesin, a complex of several proteins (Ji *et al.*, 2016; Hirano, 2015; Nasmyth and Haering, 2009; De Wit *et al.*, 2015). Recent work also suggests that the cohesin loading complex localizes near the transcription initiation sites, thus it is plausible that the extrusion process begins in the vicinity of actively transcribed genes (Busslinger *et al.*, 2017). The LEF then begins to traverse along the chromatin with a biased rate of hopping between adjacent beads, where (for illustration) the forward rate r_+ on the right side hops faster than the reverse rate (r_-) on the left hand side. (Here we presume the beginning of the chain to be on the left). This motor behavior is known to occur with transport of cargo on microtubules (Vallee *et al.*, 2004; Hirokawa and Takemura, 2005). The extrusion process stops when cohesin reaches the insulator (also called boundary element) or another cohesin ring traversing in opposite direction (Fudenberg *et al.*, 2016). How cohesin slides along DNA is still an open question; however, it was recently postulated that this role can be fulfilled by RPol2 (Davidson *et al.*, 2016).

Strings and Binders Switch Model

The strings and binders switch (SBS) model (Barbieri *et al.*, 2012, 2013a, 2013b; Chiariello *et al.*, 2016; Bianco *et al.*, 2016) is worked out from the concepts of chemical equilibrium and the polymer physics of many body interactions containing various components. In its simplest form shown in Fig. 10, one imagines a polymer chain composed of beads (green and maroon circles)

Fig. 10 The strings and binder switch (SBS) model. The green beads are effectively non-interacting, the maroon beads mark the binding sites (a CTCF-like binding sites), and the blue beads indicate the binder (cohesin-like unit). The unfolded chain is shown in A. There are two general pathways; ABCD and AEFG. These pathways are relatively mutually exclusive; however, B, C, E and F are all potential initial directions for the SBS to go and they exist in competition with one another in thermodynamic equilibrium.

where the green beads are effectively non-interacting elements and the maroon beads tend to bind with the mobile factor (represented as blue beads). The analogy is that the maroon beads would resemble something like the CTCF binding sites and cohesin, and the blue beads would represent the CTCF/cohesin binder. The system is in equilibrium, meaning that there is dynamic exchange between all the possible configurations shown in the Figure. In Fig. 10, the pathways of ABCD form one way that the strings and binders can combine; however, additional states might be also present like in pathway AEFG. Note that the arrows indicate that everything is in equilibrium. Each binding configuration resembles a switch that can be turned on and off for a given pattern.

One clear difference between the strings and binder model and the loop extrusion model is that the loop extrusion model presumes that the cohesin-like system forms an ATP-driven molecular machine that begins with binding between adjacent beads and mechanically extends in both directions until it encounters a CTCF-like obstruction. Hence, in its most rigid form, the structure in Fig. 10(G) would not form. However, in the earliest version of this model (Alipour and Marko, 2012), it was assumed that somehow the machine could skip positions. Since the precise hopping mechanism is not established, there is no reason presently to assume any restrictions per se. On the other hand, because there are many more possibilities for the dynamics of the chromatin contacts in the SBS model, the model often requires that the binding sites and binders are distinguishable and relatively mutually exclusive.

Summary

In this review, we have briefly indicated the critical features of chromatin structure, the interactions and relationships between enhancers and inhibitors, the role of CTCF proteins in forming the overall architecture of the chromatin, the volume of the nucleus using various experimental techniques, the essential methods of measuring chromatin structure and finally some examples of computational models. In the study of genomics, our understanding of how expression is regulated and how the regalia of spliceosome proteins, transcription factors, promoters and RNA polymerase II interactions will be greatly enhanced as our knowledge of chromatin binding structures and their control and regulation grows. Ultimately, it is increasingly clear that the genome is not an amorphous blob of DNA and histones randomly squeezed into a nucleus; rather, it is a well-organized system that, while possibly lacking poster-child-like publishable shapes, still exhibits a deep and highly organized meta-structural landscape.

Nucleosome Positioning

Vladimir B Teif and Christopher T Clarkson, University of Essex, Colchester, United Kingdom

Introduction

The genome of a eukaryotic cell is stored inside the nucleus in the form of the nucleoprotein complex called chromatin. If one would gently remove chromatin from the human cell nucleus, the ~ 2 m long DNA would appear as a string with beads (nucleosomes). Each nucleosome consists of two copies of each of histones H2A, H2B, H3 and H4 (so called histone octamer) and about 147 DNA base pairs (bp) wrapped around these histones (Luger *et al.*, 1997). The distances between neighbouring nucleosomes can vary from zero to tens of base pairs (van Holde, 1989). Nucleosomes can be formed at any location along the DNA, but their positioning in the genome is not random – it is affected by the DNA sequence and other factors described below, which allow the same genome to be packed differently depending on the cell state. Nucleosome positioning determines the accessibility of DNA to transcription factors and other proteins, and is thus an important regulator of gene expression. Therefore, nucleosome positioning has been an active area of research since the discovery of the nucleosome (Kornberg, 1974; Olins and Olins, 1974). These investigations have further intensified in the 2000s with the developments of new methods allowing direct measurements of genome-wide nucleosome locations using high-throughput sequencing (Ioshikhes *et al.*, 2006b; Segal *et al.*, 2006b; Yuan *et al.*, 2005). Nowadays nucleosome positioning studies have advanced up to the level of human patients, down to single cells and cell-free DNA in blood (Snyder *et al.*, 2016).

Parameters Characterizing Nucleosome Positioning

The regulation of DNA accessibility by nucleosome positioning is performed through different mechanisms that can be characterised by the following four major parameters:

Nucleosome Dyad Positions

This term refers to the position of the center of the DNA segment symmetrically wrapped around the histone octamer (so called dyad), that can be directly measured *in vitro* or inferred from averaging in high-throughput sequencing experiments. Thus, the term “nucleosome positioning” can be understood either in its general sense (including all the parameters listed below), or in a narrow sense, referring to the location of the nucleosome dyads (see Fig. 1(A)).

Nucleosome Occupancy

This term refers to the probability of a given DNA site to be occupied by a histone octamer. It can be inferred from averaging over an ensemble of cells studied via Next Generation Sequencing (NGS) experiments. In such experiments the nucleosome occupancy at a given locus is reflected by the density of sequencing reads corresponding to the nucleosomal DNA, which determines the shape of the continuous nucleosome occupancy landscape (Fig. 1(B)).

Nucleosome Stability, Accessibility and Fuzziness

In the context of genomic nucleosome positioning, nucleosome stability is usually determined by comparing the nucleosome occupancy landscape of the same genomic region obtained at different levels of chromatin digestion. The better the correlations between nucleosome landscapes in different experiments the higher the nucleosome stability. Physically, the nucleosome stability is characterised by the energetic cost to partially unwrap the nucleosome (which depends on the DNA sequence, covalent modifications of DNA and histones, and the length of the unwrapped DNA part). This thermodynamic value can be measured directly in single-molecule experiments (Poirier *et al.*, 2008) or inferred indirectly from genome-wide experiments in the living cells. In the latter case the nucleosome stability is usually defined as a measure of its sensitivity to different levels of chromatin digestion (Chereji *et al.*, 2017; Mueller *et al.*, 2017; Teif *et al.*, 2014). One can similarly define the opposite parameter called accessibility, which refers to the probability to make the nucleosomal DNA accessible for protein binding (Mueller *et al.*, 2017). Another related parameter is called nucleosome fuzziness, which is proportional to the standard error of determining the nucleosome occupancy at a given genomic location based on the averaging of several replicate experiments (Vainshtein *et al.*, 2017) (Fig. 1(C)).

Fig. 1 Schematic representations of the main characteristics of nucleosome positioning and main factors affecting it. (A-D): Main characteristics of nucleosome positioning include the dyad position (A), nucleosome occupancy landscape (B), nucleosome stability/fuzziness (C), nucleosome repeat length (NRL) (D). (E-J): Main factors affecting nucleosome positioning include the DNA sequence affinity of the histone octamer (E), statistical positioning by the boundaries (F), covalent modifications of DNA and histones (G), interaction with linker histones (H), competition with transcription factors (I), and action of chromatin remodellers (J).

Nucleosome Repeat Length (NRL)

NRL is an integrative parameter equal to the average distance between the centres of neighbouring nucleosomes (**Fig. 1(D)**). NRL can be calculated either for large enough genomic regions or the whole genome. Genome wide average NRL depends on the cell type and state. For example, it can vary from as small as 160 bp in Yeast to up to 210 bp in human or mouse ([van Holde, 1989](#)). NRL also can change during cells differentiation ([Teif et al., 2012](#); [van Holde, 1989](#)) and can be different within the same cells in specific genomic regions, e.g., a 10-bp NRL decrease with respect to genome-average NRL has been reported near bound transcription factors CTCF or SP1 ([Teif et al., 2017](#)), and NRLs associated with transcriptionally active and inactive genomic regions are also known to be different ([Valouev et al., 2011](#)).

Genetic and Epigenetic Factors Affecting Nucleosome Positioning

Genomic nucleosome positioning is non-random, and represents a unique characteristic of a given cell state and type. Several counteracting processes affect nucleosome positioning both at the level of the genome (DNA sequence) and epigenome (beyond the DNA sequence). One can distinguish six major determinants of genomic nucleosome positioning:

- Intrinsic DNA sequence affinity of the histone octamer
- Statistical positioning of nucleosomes by genomic boundaries
- Chemical modifications of DNA or histones
- Interaction of nucleosomes with linker histones
- Binding of transcription factors and other chromatin proteins
- ATP-dependent nucleosome repositioning by chromatin remodellers

These factors will be considered in detail in the next sections.

Intrinsic DNA Sequence Affinity of the Histone Octamer

DNA has a natural affinity for histones as its backbone is constituted by negatively charged phosphate residues and can be neutralised by histones which bear positive charges. Thus, nucleosomes can form at any location, but some locations are more likely to be selected for nucleosome formation for a number of reasons. The geometry of the DNA double helix is characterised by six parameters: twist, shift, slide, roll, rise and tilt ([van Holde, 1989](#)). In the first approximation most of these parameters can be determined from the dinucleotide content neglecting the effect of longer than nearest-neighbour nucleotides either based on available crystal structures ([Olson et al., 1998](#)) or molecular dynamics simulations ([Lankas et al., 2003](#); [Lavery et al., 2010](#)). Therefore, studies of dinucleotide compositions of genomic DNA have contributed significantly to the establishment of the nucleosome positioning field. Almost 40 years ago it was noticed that genomic DNA is characterised by ~ 10 bp periodicity of dinucleotide distribution, which theoretically could play a role in histone recruitment to specific sites in the DNA ([Trifonov and Sussman, 1980](#)). Later such periodicities were indeed observed in the nucleosome core DNA sequences ([Satchwell et al., 1986](#)).

In order to find the strongest nucleosome positioning DNA sequence, *in vitro* nucleosome reconstitution via salt-dialysis was performed for a large pool of randomly generated DNA sequences ([Lowary and Widom, 1998](#)). As a result of this study the sequence named “601” (later referred to as the “Widom 601” was found to have the highest affinity for the histone octamer). Furthermore, it has been demonstrated by genome-wide sequencing that G/C rich regions have higher nucleosome density, while A/T rich regions are more nucleosome depleted ([Segal and Widom, 2009](#)). At the intermediate scale, one can distinguish longer, nucleosome-size motifs, which are either attractive for the histone octamer, such as e.g., the Widom 601 sequence ([Lowary and Widom, 1998](#)) and so called Trifonov’s “strong nucleosomes” ([Trifonov and Nibhani, 2015a](#)), or present nucleosome excluding barriers ([Drillon et al., 2016](#)). The cumulative evidence from many experiments conducted in the pre-NGS era confirmed the hypothesis that the DNA sequence at least partially affects the positions of nucleosomes. This hypothesis was further supported when first genome-wide locations of nucleosomes have been mapped ([Ioshikhes et al., 2006b](#); [Lee et al., 2007](#); [Segal et al., 2006b](#); [Yuan et al., 2005](#)). Later genome-wide studies have revealed that nucleosome positions change with cell differentiation and during the cell cycle, which has led to the refinement of the concept of DNA-sequence dependent nucleosome organization ([Schones et al., 2008](#); [Whitehouse et al., 2007](#)). It is currently believed that $\sim 9\%$ of nucleosomes are arranged consistently by the DNA sequence across different types of human cells ([Gaffney et al., 2012](#)).

Since the core histone proteins are extremely conserved among different species, the physics that determines DNA sequence preferences for the histone octamer is universal from yeast to human. However, the ensemble of nucleosomal DNA sequences can differ between species, and so are the uses of nucleosomes in gene regulation. For example, nucleosome positioning at functional genomic elements can be either favoured by default (the genomic element is always closed by the nucleosome unless active nucleosome displacement happens leading to the activation of this element), or it may be unfavourable (nucleosome depletion by default allowing TF binding to a given site unless a nucleosome is actively repositioned there). A recent study showed that the former mechanism is probably preferred in higher eukaryotes while the latter is implemented in unicellular organisms ([Tompitak et al., 2017](#)). This study reported that promoters of multicellular organisms are in general characterised by nucleosome-favouring sequences, while unicellular organisms have nucleosome-disfavouring promoters.

Statistical Positioning of Nucleosomes by Genomic Boundaries

In 1988 Kornberg and Stryer proposed that nucleosome positioning, at least to some extent, is governed by the boundary effect: nucleosomes will form ordered arrays next to any physical boundary in the genome ([Kornberg and Stryer, 1988](#)). In the post-NGS era genome-wide maps of nucleosome binding have proved this hypothesis. The average nucleosome occupancy shows regular oscillations near genomic locations that act as a boundary, such as the nucleosome depleted transcription start sites ([Mavrich et al., 2008](#)), replication origins ([Eaton et al., 2010](#)) or large DNA-bound transcription factors such as CTCF ([Cuddapah et al., 2009](#); [Fu et al., 2008](#)). Even large genomic intervals such as genes experience boundary effects by their nucleosome-depleted starts and ends ([Chevereau et al., 2009](#)). Nucleosomes are different from the analogy of “beads on the string” in that nucleosomes are not freely moving along the DNA. Indeed, nucleosome reconstitution experiments show that the nucleosome occupancy oscillations around TSS can be recapitulated *in vitro* only in the presence of ATP and energy-dependent chromatin remodellers which facilitate nucleosome movements ([Zhang et al., 2011](#)). Nevertheless, even with the non-equilibrium component introduced by chromatin remodellers, nucleosome density oscillation near genomic barriers can be quantitatively predicted from equilibrium

thermodynamics consistently with the experiments (Beshnova *et al.*, 2014; Mobius and Gerland, 2010; Riposo and Mozziconacci, 2012; Rube and Song, 2014). Interestingly, recent studies show that up to 37.5% of human nucleosome positions can be accounted for by considering boundary effects created by nucleosome-excluding sequences (Drillon *et al.*, 2016).

Chemical Modifications of DNA or Histones

Covalent modifications of DNA and histones represent a large layer of epigenetic regulation (Portela and Esteller, 2010). Most common DNA modifications are cytosine methylation and hydroxymethylation in the context of CpG dinucleotides ("CpG" means cytosine followed by phosphate followed by guanine). Histone modifications are numerous and may have combinatorial nature (several different amino acids of the same histone can be covalently modified, and different histones in the same nucleosome can carry different modifications). Epigenetic modifications are established by the "writer" enzymes, and recognized by specific "reader" proteins, which modulate the genetic program based on these modifications (Strahl and Allis, 2000). The molecular action of covalent modifications of DNA and histones is often through nucleosome repositioning. A number of statistically defined relations between nucleosome positioning and covalent chromatin modification have been reported, but there seems to be no simple code connecting DNA/histone modifications with the presence/absence of a nucleosome at a given location. For example, the action of DNA methylation is context-dependent – it is rarely seen in CpG islands and when this is observed, it is associated with recruited nucleosomes. Outside of CpG islands DNA methylation is most likely between nucleosomes (Teif *et al.*, 2014). On the other hand, DNA hydroxymethylation can decrease the nucleosome stability. A methylation/hydroxymethylation switch model has been proposed to explain some of the changes in nucleosome occupancy and stability during embryonic stem cell differentiation when an almost 10% fraction of genomic CpGs change their state from hydroxymethylation to methylation, increasing the nucleosome density of the corresponding chromatin regions (Teif *et al.*, 2014). Histone modifications also have characteristic relations with nucleosome positioning. For example, regions with "active" histone modification marks such as acetylation of histone H3 lysine 4 or 9 are characterised by lower nucleosome density, while "inactive" chromatin marks such as methylation of histone H3 lysine 9 or 27 are characterised by higher nucleosome density (Teif *et al.*, 2014).

Interaction of Nucleosomes With Linker Histones

Proteins involved in nucleosome positioning are not limited to the core histones composing the nucleosome. Nucleosome packing also critically depends on the linker histones, which belong to a class of basic nuclear proteins binding the DNA entry/exit from the nucleosome and providing a separation and interaction medium between nucleosomes in chromatin (Bednar *et al.*, 2017). It is well established that the abundance of linker histones affects the NRL (Woodcock *et al.*, 2006), which may in turn determine different types of chromatin packing (Bascom *et al.*, 2017; Routh *et al.*, 2008). Usually NRL increases with the increase of linker histone concentration in the nucleus, but it can be also affected by the competition of linker histones with other abundant chromatin proteins (Beshnova *et al.*, 2014).

Binding of Transcription Factors and Other Chromatin Proteins

Transcription factors (TFs), which bind DNA sequence-specifically, can affect nucleosome positioning in a number of ways considered below (see Fig. 1(E)–(J)).

TF Competition With Histone Octamer

The energy of complete nucleosome unwrapping or partial dissociation of the histone core from the DNA is much larger than typical energies of TF-DNA binding. Therefore, for most TFs nucleosomes can be viewed as almost immobile obstacles that do not really compete with TFs on a timescale of usual TF binding to the DNA. If TF/nucleosome arrangement would have been determined by equilibrium thermodynamics, nucleosome positioning would be determining TF binding and not the other way around (Teif and Rippe, 2010). Only few chromatin proteins such as CTCF have DNA binding energy comparable to that of the histone octamer, allowing them to act as a boundary affecting up to several nucleosomes in its vicinity (Cuddapah *et al.*, 2009; Fu *et al.*, 2008). It is important to keep in mind that the chromatin is never in a true thermodynamic equilibrium, and thus active energy-dependent processes, as well as the kinetics of binding determine the order of events in terms of the nucleosome/TF competition (Table 1).

TF Binding to DNA Partially Unwrapped From the Histone Octamer

Since the nucleosome is not a single entity, it can "breathe" by partially uncoiling the nucleosomal DNA. Transcription factors then can bind the nucleosomal DNA, depending on how far their binding site is hidden inside the nucleosome (North *et al.*, 2012). An

Table 1 Computational tools to predict nucleosome positioning (sorted alphabetically)

Description	Online/local installation	Dl(tri)nucleotide/periodicity/ specific motifs/empirical feature
FineStr : Single-base-resolution nucleosome mapping server (Trifonov, 2010; Gabdank <i>et al.</i> , 2009, 2010). The analysis is performed using the probe based on the 117-bp DNA bendability matrix derived from <i>C. elegans</i> . The authors suggested the universality of this pattern for other species. http://www.cs.bgu.ac.il/~nucleom/	+/-	+ / + / + / -
ICM Web : ICM Web allows users to assess nucleosome stability and fold any sequence of DNA into a 3D model of chromatin (Stolz and Bishop, 2010b; Sereda and Bishop, 2010). The model is displayed in the visual browser JSmol or can be downloaded. ICM takes a DNA sequence and generates (i) a nucleosome energy level diagram, (ii) coarse-grained representations of free DNA and chromatin and (iii) plots of the helical parameters (Tilt, Roll, Twist, Shift, Slide and Rise) as a function of position. http://dna.engr.atech.edu/icm-du	+/-	- / - / - / +
iNuc-PhysChem : Identifying nucleosomal or linker sequences from physicochemical properties (Chen <i>et al.</i> , 2012). The algorithm identifies nucleosomal sequences by incorporating twelve physicochemical properties defined elsewhere, such as A-phlicity, base stacking, B-DNA twist, bendability, bending stiffness, DNA denaturation energy, Z-DNA potential. The model was trained on data from <i>H. sapiens</i> , <i>C. elegans</i> and <i>D. melanogaster</i> . http://lin.uestc.edu.cn/server/iNuc-PhysChem	+ / +	+ / - / + / +
iNuc-PseKNC : A sequence-based predictor for nucleosome positioning in genomes with pseudo k-tuple nucleotide composition (Guo <i>et al.</i> , 2014). This is another software package from the developers of iNuc-PhysChem . Here, the samples of DNA sequences were formulated using six basic DNA local structural properties trained on datasets from <i>H. sapiens</i> , <i>C. elegans</i> and <i>D. melanogaster</i> . http://lin.uestc.edu.cn/server/iNuc-PseKNC	+/-	+ / - / + / +
Mapping_CC : Displays the nucleosome predictions based on the DNA dinucleotide correlation pattern. This algorithm was initially associated with one of the first high-throughput genome-wide nucleosome maps in Yeast (Ioshikhes <i>et al.</i> , 2006a). An updated version is available at http://nucbrowser.ucoz.com/load/	- / +	+ / + / - / -
MOSAICS : Methodologies for Optimization and Sampling in Computational Studies (Minary and Levitt, 2014). Perl scripts and a precompiled package to perform training-free atomistic prediction of nucleosome occupancy based on all-atom force field calculations. The effect of DNA methylation can be taken into account. http://www.cs.ox.ac.uk/mosaics/nucleosome/nucleosome.html	- / +	+ / - / - / +
NucEnerGen : Nucleosome energetics predictions based on high throughput sequencing (Locke <i>et al.</i> , 2010). It utilizes dynamic programming to calculate allowed nucleosome configurations and the Percus equation to infer sequence-dependent energies from the experimental occupancy profiles. http://nucleosome.rutgers.edu/nucenergen/	- / +	+ / + / + / -
nuMap : A web application implementing the YR and W/S schemes to predict nucleosome positioning (Alharbi <i>et al.</i> , 2014; Cui and Zhurkin, 2010, 2014). The methodology is based on the sequence-dependent anisotropic bending, which dictates how DNA is wrapped around a histone octamer. This application allows users to specify a number of options such as schemes and parameters for threading calculation and provides multiple layout formats. http://numap.rit.edu/app/dna/index.xhtml	+/-	+ / + / - / +
NuPoP : Nucleosome Positioning Prediction Engine (Xi <i>et al.</i> , 2010; Wang <i>et al.</i> , 2008). NuPoP is built upon a duration hidden Markov model, in which the linker DNA length is explicitly modeled. NuPoP outputs the Viterbi prediction, nucleosome occupancy score (from backward and forward algorithms) and nucleosome affinity score. NuPoP has three formats including a web server prediction engine, a stand-alone Fortran program, and an R package. The latter two can predict nucleosome positioning for a DNA sequence of any length. http://nucleosome.stats.northwestern.edu	+ / +	+ / + / - / -
Nu-OSCAR : Nucleosome-Occupancy Study for Cis-elements Accurate Recognition. It is devoted to identifying binding sites of known transcription factors, which further incorporates nucleosome occupancy around sites on promoter regions. The derivation of the algorithm is based on a biophysical view of interactions between protein factors and nucleosome DNA. http://bioinfo.au.tsinghua.edu.cn/nu_oscar/oscar.html	+/-	+ / + / - / -
nuScore : A nucleosome-positioning score calculator based on the DNA curvature properties (Tolstorukov <i>et al.</i> , 2008). This software allows an important type of analysis, where a user enters many sequences to calculate the average nucleosome energy profile. http://compbio.med.harvard.edu/nuScore	+/-	+ / + / - / +
N-score : MATLAB and Python codes using a wavelet analysis based model for predicting nucleosome positions from DNA sequence (Yuan and Liu, 2008). http://bcb.dfci.harvard.edu/~gcyuan/software.html	- / +	+ / + / - / -

effect called “collaborative competition” allows two TFs help each other to bind the nucleosomal DNA, because it is easier to the second TF to bind if the first TF is already bound and the DNA is already partially unwrapped from the nucleosome (Polach and Widom, 1996). This can lead to nonlinear effects of nucleosome positioning at regulatory sites such as enhancers (Mirny, 2010; Teif and Rippe, 2011).

TF-Mediated Recruitment of ATP-Dependent Enzymes

Sequence-specific binding of transcription factors can be used as a strategy to recruit to a given site an enzyme that chemically modifies DNA or histones, or actively translocates the nucleosome (Agalioti *et al.*, 2000). More details on this effect can be found in the next section.

ATP-Dependent Nucleosome Repositioning by Chromatin Remodellers

Random sliding of nucleosomes along the DNA is very slow at physiological conditions, and this effect is mostly limited to in vitro studies (Meersseman *et al.*, 1992), while nucleosome repositioning in live systems is usually an active process requiring ATP-dependent molecular motors, so called chromatin remodellers (Clapier *et al.*, 2017). For example, it has been shown that the oscillatory nucleosome density pattern near Yeast promoters can be recovered by in vitro nucleosome reconstitution on the same DNA sequences only in the presence of the cell extract and added ATP (Zhang *et al.*, 2011). In the absence of ATP the remodeller activity is abolished and nucleosome positioning tends to reflect the thermodynamically favoured pattern. Remodellers can act both in favour and against the thermodynamically preferred pattern depending on the context. A simplistic mathematical representation of remodeller rules is that a remodeller randomly binds a nucleosome, and then depending on the remodeller type, DNA sequence and chromatin context it either moves the nucleosome left/right, or evicts it completely (Teif and Rippe, 2009). Remodellers usually move nucleosomes in discrete steps such as 5 or 10 base pairs along the DNA, which is explained by the mechanics of the double helix repositioning along the nucleosome through formation of small loops relocated along the histone octamer (Clapier *et al.*, 2017). In many instances remodellers bind their target nucleosome non-randomly, and their recruitment is achieved by multiple remodeller subunits that recognize certain TFs or histone modifications (Ho and Crabtree, 2010).

Theoretical Approaches to Predict Nucleosome Positioning

Computational algorithms for predicting nucleosome positions can be roughly categorized into biophysical (taking into account physical properties of DNA and histones), bioinformatical (learning the rules of preferred nucleosome distributions without knowing details of molecular interactions), and hybrid models representing the mixture of these two approaches. A list of more than 20 web servers that offer nucleosome positioning prediction has been compiled elsewhere (Teif, 2016).

In typical bioinformatics-inspired models no assumptions are made about the underlying forces that determine nucleosome positions. Instead, features of the DNA content are analysed for available experimental nucleosome positioning datasets and it is assumed that nucleosome positioning in other systems follows the same rules. For example, the nucleosomal and linker DNA sequences can be collected from experiments in order to be able to find some common themes in these genomic features, and then analysed using e.g., wavelet analysis to detect changes in di-nucleotide frequency allowing to distinguish between linker and nucleosomal sequences (Yuan and Liu, 2008). The problem with training a model based on nucleotide content is that there are 4^{147} possible arrangements within a 147 bp DNA window, which is larger than the length of any known eukaryotic genome. Even if the model is trained on many datasets from different genomes, these still do not cover all possible nucleotide combinations that can be theoretically encountered. For this reason, models trained on one species are in general expected to underperform on other species (Kaplan *et al.*, 2009b), although few universal nucleosome sequence combinations are also expected (Trifonov and Nibhani, 2015a).

In typical biophysical models the prediction of nucleosome positioning is based on available nucleosome crystal structures to infer bending energies corresponding to all dinucleotides and then calculate the nucleosome score for each sliding window of 147 bp with a given dinucleotide distribution. In contrast to bioinformatics models which are trained on data that may or may not be representative of all genomic sequences, biophysical models are based on the assumptions about the underlying molecular dynamics of the process of nucleosome formation (Chereji and Morozov, 2015; Chevereau *et al.*, 2009; Stolz and Bishop, 2010a; Tompitak *et al.*, 2017). Most biophysical models are quite demanding in terms of the computational power if they perform realistic simulations. The power of these models is that they allow connecting intrinsic DNA sequence affinities with active repositioning scenarios such as TF/nucleosome competition and remodeller action (Teif and Rippe, 2009). Furthermore, biophysical models allow treating such basic phenomena as statistical nucleosome positioning by the boundary (Chevereau *et al.*, 2009), the exclusion of nucleosomes by their neighbours (Segal *et al.*, 2006b) and partial nucleosome unwrapping (Teif and Rippe, 2011). In principle, biophysical models allow treating any level of complexity in nucleosome positioning, provided there is a way to parameterise the models based on some experimental data. The latter is frequently becoming the bottleneck.

Future Directions

The number of computational algorithms and experimental datasets devoted to nucleosome positioning continues to increase, but the fundamental questions of how to predict nucleosome cell type/state-specific nucleosome re-positioning and the corresponding changes in gene expression are still not solved. One major complication is that the rules of chromatin remodelling are difficult to derive from experiments. Another complication is that even when the remodeller rules will be determined experimentally, it will be still a challenge to integrate them in the computational models where both equilibrium and non-equilibrium processes coexist. A third complication is the 3D genome structure – nucleosome positioning happening in the 1D is influenced by and influences the 3D chromatin packing. In order to address these challenges one can expect three major directions of the nucleosome positioning field. Firstly, new high-throughput sequencing methods will continue to emerge, with a special emphasis on single-molecule and single-patient studies. Secondly, the gap in theoretical descriptions will require developing new approaches integrating the dynamics of nucleosome positioning in the description of in vivo processes. Thirdly, new biophysical models will have to be developed to account for the interplay of the 1D and 3D nucleosome arrangements based on the experimental data on 3D chromatin packing. The latter is already a very active area of research supported by large funding initiatives (Dekker *et al.*, 2017).

Introduction

Our genome consists of a set of chromosomes where each chromosome is a linear sequence of four nucleotides A, C, G and T. This linear model organizes the genes in functional units that help to understand many biological processes and diseases. For example, the histone genes are mostly clustered in [Albig and Doenecke \(1997\)](#). We also know that genes in the same pathways are more likely to be close proximity in our genome ([Lee and Sonnhammer, 2003](#)). For disease, Down syndrome is caused by the amplification of chromosome 21. Charcot-Marie-Tooth disease type I and Hereditary neuropathy with pressure palsies are caused by duplication and deletion of [Roa et al. \(1993\)](#). Although the linear model is useful for studying our genome, the linear model is insufficient to explain every biological processes. For instance, we cannot explain how enhancers control the expressions of their target genes which can be millions base pairs away or even in different chromosomes.

One possible explanation is that our genome folds into a 3 dimensional structure. The folding brings the enhancers close to the target genes to control their expressions. It also can explain why cells of different tissue types have different expression profiles. Although the genome in different tissue cells are the same, the 3 dimensional structures of our genome are different in different tissues ([Parada et al., 2004](#)). The tissue-specific spatial organization of our genome may change the spatial distance between the enhancers and their target genes, that finally create the tissue-specific expression profile ([Krijger and de Laat, 2016](#)). Hence, decoding the 3D structure of our genome is important to learn the mystery of our life and understand diseases.

To understand the 3D organization of our genome, a few biotechnologies are developed. They can be classified into two approaches: Fluorescence in situ hybridization (FISH) and Chromosome Conformation Capture (3C).

FISH experiments use fluorescence probes to examine the co-localization of different DNA fragments with microscopies. It allows us to measure the 3D distance between two genomic loci. By the distance, we determine if these two genomic loci are interacting. However, since FISH is based on fluorescence probes, we can only measure the 3D distance of the genomic loci for a few loci. It is difficult to expand this approach to the genome-wide scale.

Chromosome Conformation Capture (3C) was proposed by [Dekker et al. \(2002\)](#). Instead of observing the 3D distance of the interacting loci, the 3C method digests the genomic DNA with enzyme, like HindIII, followed by ligation. If two different loci are spatially close, the corresponding DNA fragments have higher chance to be ligated. Using specific PCR primer pair, the interaction between the two loci can be captured. Unlike FISH, 3C cannot tell the interaction of two loci in the single cell level and the 3D distance between them. It only tells the average contact frequency.

Moreover, it is possible to enhance the 3C method to detect the genomic interactions of multiple loci. Many 3C-based methods are developed, they include: 4C (Circular Chromosome Conformation Capture ([Hakim and Misteli, 2012](#)) or Chromosome Conformation Capture-on-Chip ([Simonis et al., 2006](#))), 5C (Chromosome Conformation Capture Carbon Copy method ([Dostie et al., 2006](#))), Hi-C ([Lieberman-Aiden et al., 2009](#)) and ChIA-PET ([Fullwood et al., 2009](#)). 4C methods are used to identify the long chromatin interactions from one locus to all other loci as “one-to-all” approach. 5C method is used to identify the chromatin interactions between many loci specified by primers as “many-to-many” approach. By taking advantage of high-throughput sequencing, Hi-C and ChIA-PET were introduced in 2009 to call genome-wide chromatin interaction.

However, the raw sequencing datasets from Hi-C and ChIA-PET do not provide direct evidences of chromatin interactions. Computational methods are required to extract the interactions among loci and determine the three dimensional structure of our genome. This review aims to review the computational methods for analyzing Hi-C datasets.

The manuscript is organized as follows. We first review the experimental method for Hi-C. Then, we give an overview of the analysis pipeline for Hi-C, which consists of 7 parts. Finally, we detail the currently available tools for these 7 steps.

Review of Hi-C Experiment

Hi-C is proposed by [Lieberman-Aiden et al. \(2009\)](#). It aims to recover the genome-wide chromatin interactions. Precisely, for every two loci in the genome that are spatially close, HiC experiment will generate a chimeric DNA fragment formed by the ligation of the two DNA fragments in these two loci. The steps of Hi-C experiment are as follows. First, cells are cross-linked with formaldehyde. This ensures the interacting DNA fragment pairs are covalently linked. Then, the chromatin is digested with restriction enzyme (say, HindIII). The sticky ends are filled in with biotinylated nucleotides. Ligation is performed under extremely dilute conditions to create chimeric molecules that link the two interacting DNA fragments. These chimeric molecules represent chromatin interactions. Then, these resulting DNA fragments are purified and sheared. By pulling down the biotinylated junctions, we obtain a set of DNA fragments that are formed by connecting two interacting DNA fragments. These fragments are called Hi-C ligation products. Through high-throughput sequencing, Hi-C paired-end reads are obtained from the two ends of the Hi-C ligation products.

Overview of Hi-C Analysis Pipeline

The Hi-C experiment generates paired-end reads which provide information on chromatin interaction. The aim of Hi-C analysis is to decrypt such interactions. Hi-C analysis involves the following steps:

- (1) *Mapping*: Given a Hi-C library, this step aligns the Hi-C reads on the reference genome.
- (2) *Read-level filtering*: Some aligned read pairs may not be coming from Hi-C ligation products. This step aims to filter the noise and retain only valid Hi-C read pairs.
- (3) *Normalization*: Due to experimental noises and mapping biases, systematic errors may occur. This step aims to correct the Hi-C signal.
- (4) *Finding local structures*: Our genome is folded into multiple local structures like compartments and TADs. This step aims to call these local structures.
- (5) *Calling mid-range or long-range chromatin interactions*: Locally, the genome folds into local structure. Globally, the loci are interacted through mid-range or long-range chromatin interactions. This step aims to call these global interactions.
- (6) *Visualization*: A large number of local structures, mid-range and long-range chromatin interactions are predicted in the previous steps. To help users to study these results, a number of tools are developed to visualize those results.
- (7) *3D structure prediction*: The Hi-C experiment provides the pairwise interaction information. However, it does not explicitly report the actual chromatin structure. This step aims to predict the 3D structure based on the information provided by Hi-C.

Below, we will detail tools for these 7 steps.

Hi-C Paired Read Mapping

Hi-C paired reads are extracted from the two ends of Hi-C ligation products, where each Hi-C ligation product is formed by ligating two genomic fragments crossing a ligation junction. Depending on the location of the ligation junction, there are 5 cases as shown in Fig. 1. Mapping of such Hi-C read pair is complicated by the location of the ligation junction.

Early methods assume that, for most cases, the ligation junctions do not occur near to the ends of the Hi-C ligation products (like the form of Fig. 1(a)). Then, simple approaches (like (Yaffe and Tanay, 2011)) use the first 50bp of each read for mapping. They assume the first 50bp does not cross the ligation junction.

HiClib (also called ICE) (Imakaev et al., 2012) is the first ligation junction-aware method. It first aligns the 25bp of each read in the HiC read pair. If it is aligned uniquely, we accept the alignment. Otherwise, extends by 5bp and realign again until the read is uniquely aligned.

HiClib is slow since it requires to extend the alignment 5bp by 5bp. Later, chimeric alignment algorithms are proposed. They include: HIPPIE (Hwang et al., 2015), HiCCUPS (Rao et al., 2014), diffHic and HiC-Pro (Servant et al., 2015). These methods run STAR, BWA or Bowtie2 to align the read pair first. If both reads align uniquely, the alignment is done. Otherwise, one of the reads is soft-clipped. These methods trim the reads and realign the clipped portion with the potential to identify the ligation junction.

Read-Level Filtering

After read mapping, the uniquely mapped paired-end reads are subjected to read-level filtering. The read-level filtering removes paired-end reads that are not coming from Hi-C ligation products. These noisy paired-end reads include:

- (1) Self-ligation read pairs: Self-ligation product is formed by a DNA fragment that is circularized and self-ligated. The corresponding paired-end read forms an outward alignment and has short insert size.
- (2) Dangling read pairs: Dangling product is a normal DNA fragment with no ligation. The corresponding paired-end read forms an inward alignment and has short insert size.
- (3) Redundant read pairs: When multiple paired-end reads map to exactly the same genome location, these are redundant read pairs generated by PCR amplification.
- (4) Random breaking read pairs: A random breaking read pair Paired alignments where both ends are far from restriction enzyme cut sites:

Fig. 1 Possible forms of Hi-C ligation product formed by ligating the blue and red DNA fragments. Depending on the location of the ligation junction, there are 5 forms. (a) is the common form where the ligation junction is in the middle, and is not covered by the sequenced reads, (b) is the form where the ligation junction is near to the left end and covered by one of the reads in a pair, (c) is the form where the ligation junction is near to the right end and covered by one of the reads in a pair, (d) and (e) are the form where there is no ligation.

In this step, the alignment of every read pair is examined. If the read pair is classified as self-ligation read pair, dangling read pair, redundant read pair, or random breaking read pair, it is filtered.

The read-level filtering is implemented in a number of software. They include: HICUP (Wingett *et al.*, 2015), HiC-inspector, HiC-Box, HiCdat, HiCLib (Imakaev *et al.*, 2012), HiC-Pro (Servant *et al.*, 2015), HIPPIE (Hwang *et al.*, 2015).

Hi-C Data Normalization

Due to biases in the wet-lab steps and mapping, the Hi-C paired reads are also biasedly mapped on the genome. One (arguably the most) important step is to normalize the Hi-C signal. There are two approaches: (1) explicitly model the biases and (2) matrix balancing approach.

Yaffe and Tanay (2011) proposed Hicpipe to explicitly model the biases. For any two fragment ends a and b , they observed three types of biases:

- (1) Mappability: For any fragment end x , the mappability $M(x)$ is defined to be the proportion of loci in $[x-500, x+500]$ that can be uniquely aligned. Yaffe and Tanay observed that the number of interaction reads between two fragment ends a and b is proportional to $M(a)M(b)$.
- (2) GC content of the fragment ends: Yaffe and Tanay observed that GC content around the fragment ends affects the ligation efficiency.
- (3) Fragment length: Restriction fragment length is the length of the fragment after cutting the genome with the restriction enzyme. Yaffe and Tanay observed that restriction fragment length affects the ligation efficiency.

By analyzing these three biases, Yaffe and Tanay (2011) proposed a model to compute the by-chance probability of the interaction of two fragment ends. Normalized contact map is computed by dividing the observed number of contacts between 1-Mb chromosomal bins by the expected number of contacts predicted by the model.

HiCNorm (Hu *et al.*, 2012) is another method for normalizing the contact map. It also aims to remove the above three biases. HiCNorm uses a generalized linear regression-based method. HiCNorm directly models the contact frequency between two bins using Poisson or negative binomial distribution, which simplify the set of parameters. Hence, HiCNorm is computationally more efficient. A few pipelines use HiCNorm for normalization. They include: HiCdat (Schmid *et al.*, 2015), HIPPIE (Hwang *et al.*, 2015).

Apart from explicitly models the biases, another approach is called matrix-balancing approach. The matrix-balancing approach does not assume the knowledge of the sources of biases. It assumes that, in the “true” model, every locus has the same number of interactions with other genomic regions. This is known as the equal visibility assumption.

Under the equal visibility assumption, the simplest solution is to use vanilla coverage (Lieberman-Aiden *et al.*, 2009). Consider any two bins i and j , suppose the observed number of paired end reads between two bins i and j is $O(i,j)$. Then, the number of paired end reads with one end in bin i is $O(i) = \sum_j O(i,j)$. The normalized count between two bins i and j is $N(i,j) = \frac{O(i,j)}{O(i)O(j)}$.

Vanilla coverage is not good enough, since the noise in the original interaction frequency will affect the normalized count significantly. Later, ICE (Imakaev *et al.*, 2012) is proposed. ICE is an iterated version of Vanilla coverage. It repeatedly runs Vanilla coverage until the signal is converged. A few methods use ICE for normalization. They include: HiCdat (Schmid *et al.*, 2015), Fit-Hi-C (Ay *et al.*, 2014), HiC-Pro (Servant *et al.*, 2015), HOMER (Heinz *et al.*, 2010).

Local Structure Calling

The 3 dimensional structure of our genome has two levels of structures: local and global structures. Locally, our genome is folded into multiple hierarchical of local structures, from compartments (Lieberman-Aiden *et al.*, 2009) to TADs (Dixon *et al.*, 2012) and nested sub-TAD (Rao *et al.*, 2014). Then, those local structures interact and form the global structure. Here, we detail the local structure calling methods.

Compartments partition the genome into regions with high frequency of interactions and regions with low frequency of interactions. The initial approach (Lieberman-Aiden *et al.*, 2009; Imakaev *et al.*, 2012) uses principal component analysis (PCA) to identify them. Given the normalized contact probability T_{ij} for every pair of bins i and j , $T_{ij} = \sum_{k=1}^N \lambda_k \cdot E_i^k \cdot E_j^k + \bar{T}$, where $\bar{T}$ is the mean value of T , λ_k is the Eigen value and E^k is the Eigen vector. It is observed that the first Eigen vector divides the genome into compartments with high and low frequency of interactions (Sometimes, the first Eigen vector represents the short and long chromosome arms. In this case, the compartments are represented by the second Eigen vector.) Compartments typically are of size several megabases. Compartments with high frequencies of interactions correspond to Euchromatin region with high density of genes while compartments with low frequency of interactions correspond to heterochromatin and is largely made up of gene deserts.

Using Hi-C data, Dixon *et al.* (2012) visualized 2D-interaction matrices using a variety of bin sizes. They noticed that at bin sizes less than 100kb, highly self-interacting regions begin to emerge (triangles in the heatmap, see Fig. 2). These regions are termed as “Topologically-Associated Domain” (TAD). Many methods are proposed to call TADs. They include: DomainCaller(DI/HMM) (Dixon *et al.*, 2012), Insulation score (Crane *et al.*, 2015), Armatus (Filippova *et al.*, 2014), HiCseg (Levy-Leduc *et al.*, 2014), DomainCaller (Dixon *et al.*, 2012), TopDom (Shin *et al.*, 2016), IC-Finder (Haddad *et al.*, 2017), TADbit (Serra *et al.*, 2017) and HiFive (Sauria *et al.*, 2015).

Fig. 2 This is the visualization of the 2D-interaction matrices of chr19 using bins of size 25 k. A number of self-interacting regions (as visualized as triangles) are observed. (The figure is generated using 3D Genome Browser. Reproduced from Wang, Y., Zhang, B., Zhang, L., *et al.*, 2017b. The 3d genome browser: A web-based browser for visualizing 3d genome organization and long-range chromatin interactions. bioRxiv).

Rao *et al.* (2014) observed that within a TAD, it contains some smaller structures called subTADs. Juicer (Arrowhead) (Rao *et al.*, 2014), TADtree (Weinreb and Raphael, 2016), CaTCH (Zhan *et al.*, 2017), HBM (Shavit *et al.*, 2016), and HiTAD (Wang *et al.*, 2017a) are developed to predict these subTADs.

Recently, Forcato *et al.* (2017) and Dali and Blanchette (2017) have assessed the performance of these methods. Since different TAD prediction tools are based on different assumptions, they report different sets of TADs. In the future, more works are needed to improve the predictions of TADs and subTADs.

The above methods predict TADs using Hi-C data only. There are methods that predict TADs using other omics datasets. One example is HubPredictor (Huang *et al.*, 2015), which predicts TADs using both Hi-C and histone mark ChIP-seq data.

Calling Mid-Range or Long-Range Chromatin Interactions

Our genome locally forms structures like compartments, TADs and subTADs. Globally, the loci are interacting through mid-range or long-range chromatin interactions. A number of methods have been proposed to call these global interactions.

Duan *et al.* (2010). gives the early method to call global interactions. A background expected contact frequency is learnt for each genomic distance. When the actual contact frequency between two loci is higher than expected, these two loci are deemed to be interacting.

After that, a number of papers are proposed for calling global interactions. The major improvement is on the modeling of the background contact frequency. AFC (Jin *et al.*, 2013) models the background contact frequencies as a negative binomial distribution and a global background model was devised that consists of both systematic bias factors and the linear genomic distance factor. Fit-Hi-C (Ay *et al.*, 2014) uses a non-parametric spline approach to model the background-chromatin contact frequency. The above two methods have many false positives. GOTHIC (Mifsud *et al.*, 2017) stated that the background contact frequency also depends on the read coverage. It improves the global background interaction frequency of two loci to depend also on the relative genome-wide coverage.

All above methods assume the chromatin interaction frequencies for different loci pairs are independent. Instead of assuming a global background, HiCCUPS (Rao *et al.*, 2014) uses a combination of local and global background to model the contact frequency. HMRF (Xu *et al.*, 2016a) proposed to use a hidden Markov random field based Bayesian method to explicitly model the spatial dependency among adjacent loci. HMRF is slow. The same authors proposed FastHiC (Xu *et al.*, 2016b), which uses a simulated field approximation to approximate the joint distribution of the hidden peak status by a set of independent random variables, leading to more tractable computation.

Visualization

After the Hi-C data is processed, local structures like TADs and subTADs, mid-range and long-range chromatin interactions are predicted. To help the users, it is good to visualize them. A number of software is available for Hi-C data visualization. First, we can

use traditional genome browser to visualize the Hi-C data. These browsers include: USCS genome browser, Ensembl, Integrated genome browser (IGB), Integrated genome viewer (IGV), etc.

Some specialized visualization tools for HiC data are also available. They include: WashU Epigenome Browser (Zhou *et al.*, 2013), CytoHiC (Shavit and Lio, 2013), HiCPlotter (Akdemir and Chin, 2015), QuIN (Thibodeau *et al.*, 2016), 3D Genome Browser (Wang *et al.*, 2017b). WashU Epigenome Browser is modified that allows us to view long-range contact data. CytoHiC is a Cytoscape plugin that allow users to view and compare spatial maps of genomic landmarks, based on normalized Hi-C datasets. HiCPlotter and 3D Genome Browser are simple tools that visualize Hi-C data as a Hi-C matrix. QuIN (Thibodeau *et al.*, 2016) represents the Hi-C interactions as a network. Precisely, the genomic loci are represented as vertices while the interactions between two genomic loci are represented as edges.

3D Modeling

The above steps extract interactions among pairs of loci. They did not recover the actual three dimensional structure of the genome. This step aims to reconstruct the three dimensional chromatin structure from the pairwise interactions predicted from Hi-C data. Given the contact frequencies among the genomic loci, most existing methods run in two steps. The first step is to convert the contact frequency between any two loci into their spatial distance. Then, the second step learns the 3D structure from the spatial distance matrix. There are two approaches for the second step: Consensus approach and ensemble approach.

Consensus approach uses the spatial distance (or the contact frequency directly) as the constraint, then the 3D structure is reconstructed. This approach is first used by Duan *et al.* (2010). Then, a number of methods are developed using the same approach. They include: (Tanizawa *et al.*, 2010), ChromSDE (Zhang *et al.*, 2013), ShRec3D (Lesne *et al.*, 2014), 3D-GNOME (Szalaj *et al.*, 2016), PASTIS (Varoquaux *et al.*, 2014), and HSA (Zou *et al.*, 2016).

Another approach is ensemble approach. Observe that the chromatin interactions extracted from the Hi-C experiment are actually the interactions from a pool of millions of cells. The conformations in different cells are different. The ensemble approach aims to produce a set of 3D models which can fit the observed contact frequencies. There are two strategies. The first strategy identifies multiple independent models that can fit the Hi-C data. Hence, this strategy can identify multiple models instead of just one local optimal model. Trieu and Cheng (Trieu and Cheng, 2014), MOGEN (Trieu and Cheng, 2016), LorDG (Trieu and Cheng, 2017), AutoChrom3D (Peng *et al.*, 2013), (Bau and Marti-Renom, 2012) (and TADbit (Serra *et al.*, 2017)), MCMC5C (Rousseau *et al.*, 2011) use this strategy.

Another strategy finds multiple models that can fit the Hi-C data in a coordinated manner. BACH-MIX (Hu *et al.*, 2013) uses MCMC to find a mixture of models that can fit the Hi-C data. InfMod3DGen (Wang *et al.*, 2015) uses EM algorithm to infer an ensemble of models that best fit the data. Other methods include Kalhor *et al.* (2011)

Summary

Understanding the 3 dimensional organization of the genome is an important topic. We started to understand that our genome is not simply organized linearly. Instead, our genome is folded into local structures called TADs; then, the local structures are interacting through mid-range and long-range interactions. Researchers found that the 3 dimensional structure of our genome can help to explain different biological processes like the enhancer and promoter interaction and the tissue-specific expression profiles.

In the last decades, many tools have been developed to recover the three dimensional structure of our genome. Although those tools provide useful information, the predictions are still far from accurate. In the future, more works need to be done.

Introduction

Since the elucidation of the double-helix as the structure of DNA in biological systems, and the advent of genetic engineering techniques in laboratory science, DNA has been at the forefront of the mind of many scientists. However, RNA has for long served as a central character in the process of life. This can be easily seen in the central dogma which states that DNA is transcribed into RNA and RNA is translated into protein (Crick, 1970). Whereas DNA maintains and replicates the information, it requires an intermediary, RNA, in order to produce protein. Indeed, RNA can perform the functions of DNA as a repository of information and template for replication, as well as catalyze chemical reactions in the form of a ribozyme (Serganov and Patel, 2007). Moreover, RNA is capable of regulating itself from various feedback and feed forward loops. Furthermore, RNA's ability to form secondary structure, which allows it to fold into tertiary structure, makes it a good structural molecule in large protein complexes ranging from those needed in transcription to capping the ends of telomeres (Azzalin *et al.*, 2007; Lodish *et al.*, 1995). Because RNA can perform so flexibly and has been so well conserved, it has been speculated that evolution began with RNA in a RNA world and only later evolved to include DNA and protein (Neveu *et al.*, 2013). It should be no surprise that even the founding group of molecular biologists in the 1950s (James D. Watson, George Gamow, Sydney Brenner and others) formed their club with the name "RNA tie club" rather than DNA (Kay, 2000). Basic fundamental discoveries concerning the structure, function, and roles of RNA in cellular systems continue to amaze and surprise.

Theoretical Background

Transcription

The process of transcription describes the steps required to copy the genetic information encoded in DNA to RNA. Each step involves specific chemical reactions and actions at the subcellular level to bring molecular components together to form these reactions. RNA (ribonucleic acid) differs from DNA (deoxyribonucleic acid) by having a hydrogen atom in the 2' position of the ribose sugar. However, both form polymers based on the ribose sugar backbone and connecting phosphodiester bonds with orientations at 5' and 3' ends. In transcription, the thymidine residue of DNA is replaced by uracil in RNA. Transcription occurs in 4 discrete steps: initiation, promoter escape, elongation, and termination (Kaiser *et al.*, 2007). Initiation describes the step where double stranded DNA, which is wrapped around histones becomes unwound and accessible to the transcription initiation complex (Murakami *et al.*, 2002a,b; Sainsbury *et al.*, 2015). This complex consists of a large number of proteins and ribosomal RNA factors that separate the double stranded DNA and begin synthesizing a RNA polymer complementary to the DNA sequence. The initiation site on DNA is defined by a promoter sequence, CpG islands, and a transcription factor binding site on the double stranded DNA that is proximal, and enhancer DNA sequences that are distal to the initiation site. Activators, co-activators, repressors, and co-repressors are proteins that form part of the transcription initiation complex and provide an additional level of control (Juven-Gershon and Kadonaga, 2010; Ptashne and Gann, 1997). Promoter escape describes the step where the RNA polymer has begun to be synthesized (Dvir, 2002). A RNA polymerase recruited by the transcription initiation complex synthesizes a RNA strand in reverse complement (A→U, C→G, G→C, T→A) using one DNA strand as the template. RNA is synthesized as antiparallel: 5' to 3' orientation. The DNA template used is termed the antisense DNA strand and the opposite DNA strand the sense strand. Different classes of RNA molecules are synthesized depending upon the RNA polymerase used: RNA polymerase I synthesizes ribosomal RNA (rRNA), RNA polymerase II synthesizes messenger RNA (mRNA), and RNA polymerase III synthesizes tRNA as well as other small RNAs. After a ~15-mer RNA nucleotide is synthesized, the RNA polymerase may continue. At this step, promoter escape is completed and elongation begins (Fouqueau and Werner, 2017). Transcription termination following elongation of the RNA strand is signalled by DNA sequences downstream of the promoter and results in RNA polymerase stopping its synthesis (Richard and Manley, 2009). The DNA sequences recognized by the transcription initiation complex to the termination signal define a transcription unit and are also referred to as a genes (Alberts, 2007). Post-transcriptional processing of newly synthesized RNAs occurs following termination. These include chemical modifications to RNA such as 5' capping, polyadenylation, and splicing of mRNAs, RNA editing, and degradation. Regulatory processes that influence the synthesis and abundance of RNAs that occur before and during transcription are termed pre-transcriptional and transcriptional regulation, respectively, while those that occur after the RNA has been synthesized are termed post-transcriptional (Jacob and Monod, 1961). Prokaryotes differ from eukaryotes in transcription by less complexity, but basic principles are maintained (Eick *et al.*, 1994). Some RNA based viruses use RNA as the template in transcription (Baltimore, 1971). Reverse transcription describes the process where RNA serves as the template for the synthesis of DNA (Baltimore, 1970; Temin and Mizutani, 1970). It has been estimated that greater than 85% of an eukaryotic genome is transcribed into RNA at some time during the life of the organism (Hangauer *et al.*, 2013).

Major RNA Classes

While most RNA classes have been historically defined by their chemical and functional properties, the power of next-generation sequencing has blurred some of these distinctions. A recent example shows how a single molecule can be classified as either an eRNA or lncRNA (Espinosa, 2016; Paralkar *et al.*, 2016). RNA classes may also be defined via the proteins family members they bind such as Argonautes to distinguish between miRNAs and piRNAs (Meister, 2013). Below, we list major RNA classes as defined in the current literature.

mRNA – messenger RNAs represent protein coding and noncoding RNAs transcribed by RNA polymerase II. They are capped by addition of a methyl-7 guanine moiety and modification of 2'-O-methyl ribose (Fabrega *et al.*, 2004; Kiss, 2001). After synthesis, adenine ribonucleic acid residues (poly A +) are added by polyadenylate polymerase via a complex that recognizes a poly A signal sequence (AAUAAA) in the last 10–30 nucleotides of the mRNA (Colgan and Manley, 1997). The poly A + mRNA is exported from the nucleus to the cytoplasm where it is edited to remove introns and splices together the exons. These edited mRNA molecules are translated into proteins by ribosomes located either in rough endoplasmic reticulum or in the cytosol (Stephens *et al.*, 2008). Noncoding RNAs may undergo further processing. It is estimated that humans have around 20,000 protein coding genes which may be sliced and edited to form approximately 10 different forms for each gene on average.

tRNA – also known as transfer RNA, it is the adaptor molecule that translates triplet codon information from mRNA to amino acid. It is part of the translation machinery called the ribosome that also contains ribosomal RNAs and proteins. The size of a tRNA is ~75 to 90 nucleotides. tRNAs are transcribed from clusters in the genome by RNA polymerase III and is highly conserved across species (Sharp *et al.*, 1985).

rRNA – also known as ribosomal RNA, it is a structural molecule that forms the ribosomal complex responsible for translating mRNA into protein (Palade, 1955). The ribosomal complex consists of multiple rRNAs and over a dozen proteins depending upon the species, along with tRNAs (Wilson and Doudna Cate, 2012). rRNAs are also highly conserved and present in all taxa and therefore are often used in evolutionary studies (Woese, 1987). rRNA is the most abundant class of RNAs and constitutes ~50% of all RNA species in a cell. rRNAs range in size from 1.5 to 5 kb (Noller, 1991).

Ribozymes – these are RNA molecules that have catalytic ability, typically to generate RNA polymers by ligating or cleaving RNA fragments together or in the ribosome to catalyze protein peptide production (Guerrier-Takada *et al.*, 1983; Kruger *et al.*, 1982). Ribozymes can be very small: around 50 nucleotides in total. Ribozymes were originally naturally occurring RNA molecules, however, they have been actively pursued and engineered as biotechnology products especially to cleave unwanted RNA molecules such as from viruses or those generated in diseases (Pyle, 1993).

eRNA – enhancer RNAs are recently discovered non coding RNAs transcribed from enhancer regions (Kim *et al.*, 2010). They are short sequences and form multiple overlapping transcripts that are not typically spliced or polyadenylated. They commonly occur at distal enhancers several kb away from the promoter and are believed to act by aiding in the recruitment of co-activators to the transcription initiation complex (Kowalczyk *et al.*, 2012). The size of eRNA varies but can be as short as 50 nucleotides and as large as several kb (Natoli and Andrau, 2012).

lncRNA – long non-coding RNAs define a class of RNAs that are >200 nucleotides long but do not code for proteins. It is now estimated that the human genome may contain >50,000 lncRNAs (Iyer *et al.*, 2015). They may be transcribed antisense to a coding RNA transcript or in intergenic spaces. They are polyadenylated and spliced and therefore share many of the same biosynthesis properties as mRNAs. While they are abundant, the precise functions of only a few are known, such as Xist which acts in dosage compensation of the X chromosome via recruitment of a polycomb repressor complex that lays down repressive epigenetic marks (Ballabio and Willard, 1992; Calabrese *et al.*, 2012). Another example is the telomerase RNA component, TERC that acts as scaffold and template to add DNA ends to telomeres (Greider and Blackburn, 1989; Kapranov *et al.*, 2007; Kung *et al.*, 2013).

miRNA – microRNAs are small noncoding RNAs transcribed by RNA polymerase II mostly but sometimes by RNA polymerase III as well (Borchert *et al.*, 2006; Lee *et al.*, 1993; Lee *et al.*, 2004). They may also be spliced from introns. These are termed mirtrons. They may also be transcribed in intergenic spaces. The initial transcript is a primary miRNA (pri-miRNA) and after its cleavage to a 75–90 nucleotide hairpin secondary structure, it is termed a pre-miRNA (precursor miRNA) (Ha and Kim, 2014). The finally processed 21 or 22 nucleotide form is the mature miRNA. miRNAs function as down-regulators of mRNA either pre-transcriptionally or post-transcriptionally. Human genomes may express >6000 different miRNAs with a very wide range of expression levels (Londin *et al.*, 2015). Isomeric forms of miRNAs termed isomiRs are also known to exist and are derived from differential processing of pre-miRNAs by Dicer enzyme (He and Hannon, 2004).

moRNA – microRNA off-set RNAs are small RNA fragments 15–22 nucleotides in length that are derived from the pre-miRNA but are “offset” on the hairpin either located upstream of the 5p mature miRNA sequence or downstream of the 3p mature miRNA sequence (Langenberger *et al.*, 2009; Shi *et al.*, 2009). The abundance of moRNAs compared to miRNAs is very low: they typically represent <1% of miRNAs derived from the same pre-miRNA. moRNAs have been found most abundantly in stem cells, embryonic bodies, and germ cells (Asikainen *et al.*, 2015). moRNAs may act to regulate mRNA expression in molecular pathways similar or shared with miRNAs (Langenberger *et al.*, 2009; Shi *et al.*, 2009).

snRNA – small nuclear RNAs are 100–300 nucleotides in length and highly abundant in the nucleus. Their sequences are Uridine rich and they function as a scaffold in splicing introns within the spliceosome complex. snRNAs exist in riboprotein complexes termed snrps (small nuclear riboproteins). They are a family of molecules and their high abundance in cells often leads to them being used as a loading control in experiments involving quantitation of small non coding RNAs (Matera *et al.*, 2007).

snoRNA – small nucleolar RNAs are 70 nucleotides in length and processed from intron fragments. Vertebrates express several hundred snoRNAs. snoRNAs act as a guide for rRNA processing, rRNA maturation, or chemical modification of complementary sequences in rRNA (Matera *et al.*, 2007).

piRNA – piwi interacting RNAs are 26–31 nucleotide RNAs transcribed from specific loci (Saito *et al.*, 2006; Vagin *et al.*, 2006). Their sequences are highly diverse and thousands of different piRNAs may be transcribed from different regions of a chromosome. Simple model organisms like fruit flies and nematodes may express tens of thousands of piRNAs while more complex organisms like mice and humans may express even more (Das *et al.*, 2008). piRNAs typically begin with Uridine, however remaining sequences may be highly variable and no consistent secondary structure has so far been found. Their initial function has been described as inhibiting transcription of transposon sequences in the genome, but more recently they have been shown as essential for controlling transcription in sperm cells (Iwasaki *et al.*, 2015).

circRNA – circular RNAs are recently discovered covalently closed RNA molecules derived from splicing of exonic sequences of mRNA or lncRNAs (Hansen *et al.*, 2013; Memczak *et al.*, 2013). Some circRNAs also contain intronic sequences. The covalent linkage to form a circular molecule occurs via a 3–5′ or 2–5′ phosphate. Although initially found in higher organisms, they now appear to be found in a wide variety of organisms including most eukaryotes studied (Ebbesen *et al.*, 2016). While their function remains under active investigation, their high abundance in brain tissues and during development suggests involvement in specific molecular functions in particular biological processes. It is hypothesized that they may act as molecular sponges by sequestering active mature miRNAs, although other potential mechanisms of action have been suggested. Sizes of circRNAs range from less than 200 nucleotides to greater than 4 kb (Lasda and Parker, 2014; Salzman, 2016).

endo-siRNA – endogenous silencing RNAs are short ~20 to 27 nucleotide sequences that are similar to miRNAs as short RNA species that attenuate gene expression (Asikainen *et al.*, 2008; Okamura and Lai, 2008). They can be derived from dsRNA structures, but unlike miRNAs do not form hairpin structures. They may however share components of the RNA silencing machinery with miRNAs including amplification pathways and binding to Argonautes. They are highly abundant in many different species and can be found in germline cells such as sperm and thus may be important in developmental processes (Nilsen, 2008; Yuan *et al.*, 2016).

rasiRNA - Repeat associated silencing RNAs are short 24–29 nucleotide RNAs that form a related but distinct family of small noncoding RNAs. Similar to piRNAs, they act in transposon and retrotransposon silencing in the genome, but also control transcription of other repeat sequences in the genome (Aravin *et al.*, 2001). Similar to piRNAs, they bind to piwi family Argonaute proteins, but are expressed in organisms such as yeast and plants where piRNAs have not been found, and are therefore distinct species from piRNAs (Aravin *et al.*, 2001).

ceRNA – Competing endogenous RNAs comprise a class including all RNA molecules that may compete for miRNAs via complementary pairing and thus attenuate miRNA actions (Salmena *et al.*, 2011). The concept has been considered as a type of molecular sponge that absorbs miRNAs and prevents their function. The growing list of ceRNAs includes molecules from other RNA classes including mRNAs, lncRNAs, circRNAs, and pseudogenes (Hansen *et al.*, 2013). ceRNAs may also act in coordination to regulate a specific gene (Tay *et al.*, 2011) (Fig. 1).

Biological Sources of RNA

Early sources of RNA for biological study came from dissected tissues that were easily accessible, abundant, soft, non-fibrous, and were easy to homogenize in order to perform biochemical fractionations (Chomczynski and Sacchi, 1987). These tissues included liver, kidney, brain, spleen, and heart from mammals. Skin, although the most abundant organ by weight from humans was typically not used in isolations because of the presence of RNAase that degraded RNA upon contact (Probst *et al.*, 2006). As different biological questions arose and more sensitive methods for biochemical analysis developed, specific tissue regions were dissected and RNA isolated. These included different brain regions such as hippocampus from brain, lymphocytes from blood, and veins from liver. As even more tissue specific resolution was sought, laser capture microdissection methods became available and isolation of ~50 cell samples from tissues were possible (Mikulowska-Mennis *et al.*, 2002). More recently, RNA isolation from single cells has come to the forefront of experimental research (Saliba *et al.*, 2014). However, even higher resolution is still being pursued and while not routine, subcellular RNA fractions from nucleus, cytoplasm, or mitochondria to name just a few structures, have been available for many years (Derrien *et al.*, 2012).

In contrast to intracellular organelles with RNA components, an extracellular structure termed the exosome, has become an exciting and unusual place to isolate RNA (Johnstone *et al.*, 1987). Exosomes are small <150 nm lipid vesicles that contain RNA, usually miRNAs but other species as well (Valadi *et al.*, 2007). Exosomes are excreted into the extracellular space and can eventually end up in body fluids or the circulation. The body fluids from where exosomes have been isolated include blood, urine, and amniotic fluid (Keller *et al.*, 2007). The amount of exosomal RNA secreted into these tissues is small and estimates of their abundance include 1–10 ng/mL fluid such as plasma (Enderle *et al.*, 2015). Exosomal sources of RNA are different than cRNA which are cellular free RNAs which have nonspecific cellular origins. cRNAs can be isolated like DNA from a large list of body fluids including amniotic fluid, spinal fluid, saliva, tears, and breast milk (Li *et al.*, 2014a). Like DNA used for diagnostics, it is possible to isolate RNA from a fetal amniotic fluid and this species is termed cffRNA, cell free fetal RNA (Vora *et al.*, 2017). The principle advantage of isolating RNAs from body fluids is due to its noninvasive nature, thus sparing the organism from losing tissues. Moreover many of these fluids such as urine and blood are highly abundant (Gahan, 2015; Huang *et al.*, 2013).

Fig. 1 Basic biogenesis of different RNA classes. (A) Biogenesis of miRNA and moRNA. A brief cartoon shows the origin of miRNA and moRNA. miRNA is marked in orange and moRNA is marked in green. (B) Biogenesis of lncRNA. lncRNA undergoes a splicing processing event. (C) Biogenesis of snoRNA and snRNA. The left side shows snoRNAs base pairing with ribosomal RNA to guide folding and cleavage of precursor rRNA. The right side shows snRNAs removing introns from pre-mRNA. (D) Biogenesis of endo-siRNA and piRNA. endo-siRNA and piRNA are exported from the nucleus to cytoplasm and different RNA binding proteins (RBPs) (Argonaute 2, AGO2 and PIWI protein are shown as examples) are required to process them. endo-siRNA and piRNA are marked by blue and green, respectively. (E) Biogenesis of rasiRNA. The process requires the Argonaute protein AGO3, and PIWI protein. (F) Biogenesis of mRNA, eRNA and circRNA. eRNAs are transcribed from enhancer regions. Canonical splicing of mRNAs produces linear transcripts while back-splicing produces circRNAs.

Meta-samples, derived from the metagenomics field, describe samples with mixtures of organisms (Hugenholtz *et al.*, 1998). These are typically obtained from the environment such as soil or sea water, but can also be complex cellular mixtures from discrete sources such as fecal matter (David *et al.*, 2014). Both RNA and DNA can be sequenced from these samples. A classical application of sequencing RNA from these samples is to identify ribosomal RNA as these are unique identifications for species in the sample and thus make it possible to identify individual species in a population living in a complex biological mixture.

Laboratory cell culture remains one of the most common sources of RNA. These can include primary cell cultures, transformed cell cultures, and stem cell derived cultures including induced pluripotent stem cells (iPSC), embryonic stem cells (eSC), or embryoid bodies (EB) to name a few. The laboratory success in growing and maintaining these different types of cells including adherent and suspended in liquid type cultures has made these cells a very flexible and dynamic source of RNA for studies.

Fractionation and enrichment or purification of specific classes of RNAs occurs independent of the sources. A total RNA purification from a biological sample contains >80% rRNAs, while mRNA and lncRNAs together account for 1%–2% of the total RNA (Kaiser *et al.*, 2007). The amount of small RNAs by weight are less than this. mRNAs can be separated from total RNAs by isolation methods using oligodT binding to take advantage of the polyadenylation of this RNA class (Morrison *et al.*, 1979). Small noncoding RNAs can be enriched by size fractionation on columns or more cleanly by size fractionation followed by elution on polyacrylamide gels followed by elution. Any carryover DNA from these fractionation procedures are digested with an RNase free DNase. As detection methods become more sensitive, a greater amount of attention has been paid to increasing the purity of each fraction.

RNA Modifications

Chemical modifications to RNA molecules has been known for a long time, however, interest in their study has been hampered by lack of experimental tools to detect their presence and low abundance of some modifications (Song and Yi, 2017). This is now changing rapidly and with highly sensitive mass spectrometry techniques as well as other analytical chemistry methods, more than 140 chemical modifications of RNA are known of which >100 are known to occur naturally (Helm and Motorin, 2017). More than half of these modifications have been characterized on rRNA and tRNA with at least 13 described for mRNA. The most common modification for mRNA is addition of a m⁷G (methylation of guanine nucleoside moiety) cap followed on the same molecule by 2'-O-methyl (methylation of ribose 2') secondary cap (Shatkin, 1976). The purpose of this modification is to increase stability of the RNA. Similarly, tRNA has a m⁵C modification that functions to prevent degradation. The most prevalent internal mRNA modification is N(6)-methyladenosine, m⁶A (Dominissini *et al.*, 2012). The most common mRNA modification in vertebrates are adenosine to inosine (6-deaminated adenosine) which is catalyzed enzymatically via a family of adenosine deaminase acting on RNA (ADAR) proteins. This RNA modification is not randomly distributed along the transcriptome but appears to occur at double stranded RNA regions such as in 3' UTRs (untranslated regions) and miRNAs. These modifications have been shown to have effects on levels of transcripts and thus can be considered a means for post-transcriptional modification. Another abundant modification in mRNAs and lncRNAs is m⁶A (methyl-6-Adenosine) which has been shown to affect transcript stability and translation as regions in the 5' UTR and stop codons are enriched for this modification. RNA modifications at the transcriptomic level have led to the advent of a new field termed "epitranscriptomics". This field shares many similar concepts with the epigenetics field including the identification of RNA epitranscriptomic readers (Li *et al.*, 2016), writers, and erasers (Frye *et al.*, 2016). The identity of specific RNA metabolism pathways combined with transcriptome scale experiments has made this young field move very quickly.

Driving the field of epitranscriptomics is next generation sequencing. RNA modifications at a transcriptomic scale are possible by immune precipitating RNA fragments with the modification via an antibody and subsequent sequencing, commonly referred to as RIP-seq (Zhao *et al.*, 2010). Using this and modifications of this method enable single nucleotide resolution of modified RNAs. A challenge for this approach are contaminants since RNA modification events, with a few exceptions, are not very abundant in the cell. Another challenge is in mapping RNA modification events to DNA sequences, so called RNA-DNA difference (RDD) comparisons (Chi, 2017). For example, adenosine→inosine modifications can be identified by comparing RNA to DNA since adenosine base pairs with thymine and inosine pairs with adenine, cytosine, or uracil. After synthesis of cDNA from RNA for sequencing, these differences between the original DNA sequence transcribed and the RNA sequence can identify specific locations of differences. However, mapping algorithms may not correctly assign mismatched sequences.

RNA Transcriptomics Nomenclature

Gene nomenclature committees representing various scientific communities have the responsibility to produce, maintain, and update gene names. These committees are necessary to maintain the stability of gene names and to ensure their accuracy. An example of such a group is the nomenclature committee of the Human Genome Organization (HUGO) that maintains *Homo sapiens* genes (Povey *et al.*, 2001). Similar committees exist to maintain gene names for mouse, rat, and *Drosophila* scientific research communities.

In general, genes names are italicized while protein names are not. *INS* refers to the human insulin protein while *INS* refers to the human insulin gene. Gene names are one type of identifier for a gene which may have many depending upon the database. The National Center of Biotechnology Information GENE ID for human insulin is 3630, while the HUGO nomenclature committee GENE ID is 6081. Gene names provided by a nomenclature committee are useful as they provide a common identifier that may be used as a standard among many users.

Gene names are typically 3–4 letters. For example, the human insulin gene is *INS* and the human insulin receptor gene is *INSR*. Model organisms such as worms (*Caenorhabditis elegans*), and fruit flies (*Drosophila melanogaster*) have gene names provided by the phenotypes of mutants recovered from forward genetic screens and maintained by their scientific communities (Gelbart *et al.*, 1997; Stein *et al.*, 2001). Examples include *Arg⁻* for a strain requiring arginine as a phenotype in yeast, *dpy-3* for dumpy appearance in worms, and *w* or *white* for white eye in fruit flies. Names are also assigned based on orthology to other organisms such as *cyp35a* for cytochrome P450 family 35a gene in *C. elegans* (Aarnio *et al.*, 2011). In bacteria, a 3 letter designation of the molecular pathway or biological process the gene product is involved in plus a capital letter denotes a gene, for example, *hisA* for gene A of the histidine biosynthesis pathway.

RNA transcripts can always be mapped to a chromosome and nucleotide position on a sequenced genome (Hubbard *et al.*, 2002; Kent *et al.*, 2002). The units are essentially coordinates on the genome. For example, the human insulin gene is located at Chromosome 11, nucleotides 2,159,779–2,161,341. Likewise, all transcript elements such as exons, enhancers, miRNAs etc. can also be identified by their coordinates. Another coordinate system identifies the continuous sequence (contig) and the order of genes. A contig may originate artificially from a yeast artificial chromosome library, phage library, or naturally from a chromosome. For example, the *daf-2* gene of *C. elegans* can also be named Y55D5A.5 as it is 5th gene on contig Y55D5A which is derived from a yeast artificial chromosome library.

miRNA names begin with the species (*hsa-* for *Homo sapiens*), followed by miR-, and then a number (e.g., *hsa-miR-128*). The mature miRNA has the miR (uppercase R) designation while the precursor is denoted with mir (lower case r, e.g., *hsa-mir-128*)

(Griffiths-Jones *et al.*, 2006). The numbers are provided sequentially for new miRNAs, but if an ortholog exists, they will be given the same number as the other orthologs (e.g., mus-mir-128). New mir ortholog names simply require the species prefix to be changed. Numbered suffixes indicate distinct precursors from unique genomic loci but identical mature miRNA sequences (e.g., mus-mir-128-1). Lettered suffixes indicate mature miRNAs closely related but from distinct precursors (e.g., mir-128b). The final suffix is given for the side of the hairpin from which the miRNA is located: either the 5' side designated 5p or 3' side designated 3p (e.g., miR-128-1-3p) (Budak *et al.*, 2016).

Other RNA classes also have their own nomenclature and naming conventions such as those for rRNAs, lncRNAs, and piRNAs provided by the HUGO Gene Nomenclature Committee (Gray *et al.*, 2015).

Transcriptome Measurements

Three essential measurements can be made on the transcriptome level of an organism: sequence, abundance, and structure (Conesa *et al.*, 2016). From a gene's sequence, specific information regarding the transcription start site, intron-exon usage, transcript termination, sequence variation, can be determined, and gene identity and orthology can be inferred. Gene abundance measurements can be determined by the number of transcripts representing a gene sequenced while secondary structure can be determined by various programs that fold the RNA sequence based on minimal free energy constraints as well as other structural factors (Miao and Westhof, 2017). Orthology is inferred by best alignment for similarity with other nucleotide sequences from other organisms while paralogy is inferred by alignment within the same organisms to detect genes belonging to the same family (Doyle and Gaut, 2000).

Whole transcriptome sequencing is performed on a sequencing platform that integrates sample preparation protocols, sequencing chemistry and detection, and data analysis as a single activity (Korpelainen *et al.*, 2014). Each transcriptome level sequencing has its own properties, history, biases, advocates, and advantages and disadvantages. The productivity and accuracy of sequencing platforms are constantly and rapidly improving (van Dijk *et al.*, 2014). Since the chemistry and technology for sequencing DNA is more mature and advanced than RNA, transcriptomic platforms typically reverse transcribe RNA into DNA and then sequence the complementary DNA. Among the commonly used platforms are microarrays, Illumina, Ion Torrent, Pacific Biosystems, and Oxford Nanopore.

Transcriptome Sequencing Platforms

Microarrays use the chemical principle of nucleic acid hybridization (DeRisi *et al.*, 1997). For a given sequence A, C, G, and T, hybridize with their complementary nucleotides via hydrogen bonding T, G, C, and A, respectively. Short DNA fragments of known sequence or identity are bound or directly synthesized to a solid support and a fluorescently labelled cDNA reverse transcribed from an RNA sample is hybridized to the fragments on the support. Since the abundance of a specific cDNA is directly correlated with the original amount of RNA in the sample, the amount hybridized is an indicator for the abundance of an RNA sequence. Since DNA sequences bound to the solid support are known and are fixed to a specific location, the identification of the gene can be determined by the location of the hybridization signal on the support. This platform has several advantages including relatively simple workflow and chemistry for detection and analysis. It is reasonably cost effective as well and entire transcriptomes can be interrogated in single replicates for a couple of hundred dollars. A disadvantage is that sequences to be interrogated need to be determined beforehand for synthesis of the microarray, cross hybridization of cDNAs can occur, and sensitivity of detection is limited to fluorescent labelling. In the early use of microarrays, many academic labs produced and printed their own microarrays, however, the field has lately been dominated by Affymetrix due to their ability to synthesize oligonucleotides directly onto a substrate.

Next-generation sequencing technologies (NGS) exploit massively parallel sequencing by synthesis (MPSS) as a chemical principle for transcriptome level sequencing (Marioni *et al.*, 2008). In the Illumina platform, RNA isolated from a sample is fragmented, and then indexes/bar codes, sequencing primer, and amplification primers are added as an adaptor molecule to the RNA. The RNA is reverse transcribed to cDNA and a second DNA strand is synthesized to yield a double stranded DNA. This DNA molecule is amplified and then sequenced by synthesis one nucleotide at a time. After each addition a specific fluorescent signal is produced for each nucleotide.

On the Illumina platform, the number of nucleotides on a DNA fragment can be up to 200 nucleotides, however 100 is more common. The number of templates sequenced, equivalent to the number of reactions on a single chip, can reach 2×10^9 . Each sequence obtained from a template is called a "read". The number of reads can be doubled to 4×10^9 using a dual flow cell, and further can be doubled to 8×10^9 by sequencing from both ends of the DNA called paired end sequencing. This can then generate up to 1.6×10^{12} of sequence information. Since the chemical reactions occur on the chip and reactants need to be removed for each chemical reaction, the solid substrate is termed a flow cell, and each flow cell is divided into 8 lanes. Indexing allows a user to add a tag, also known as a bar code, to each RNA molecule that will be sequenced. All RNAs from a single library have a specific bar code, and this allows mixing of libraries to be sequenced on a flow cell. The result is that the 2×10^9 reaction capacity can be divided into an unlimited number of libraries to be sequenced. This allows multiplexing of reactions, but more importantly drives down the cost of sequencing on a per reaction basis. The cost per reaction which equates to a read sequence can be as low as 0.001 US cents. While this might seem very cheap per reaction, there are other viable and competitive MPSS platforms.

Among these are Ion Torrent's personal genome sequencers (Liu *et al.*, 2012; Merriman and Rothberg, 2012; Quail *et al.*, 2012). While also based on a sequencing by synthesis principle, the detection of each added nucleotide is based on the release of a hydrogen ion which occurs after each addition. A pH change is measured in real time using semiconductors that are multiplexed in the platform. The advantage of this chemistry is that no modified nucleotides are needed. If homopolymer regions are encountered, for example, TTTT regions, then multiple reactions will occur leading to bigger signals. This platform, while not generating as many reads as Illumina, has lower instrumentation cost and the total run time for generating sequence is substantially lower, for example, 2 h compared to approximately 24 h. Also, for infrequently run instruments or low through-put, it provides an advantage since it is easier to fill and run at full capacity. Length of reads is also important and Ion Torrent routinely uses 200 nucleotide reads with 400 read chemistry available. The number of reads produced on the Ion Torrent platform depends upon the chip used but can be as low as 0.5×10^6 to as high as 5×10^6 per run. At 200 nucleotide chemistry, a run generating 5×10^6 reads would produce 1×10^9 of sequence information.

Another sequencing platform is Pacific Biosystems which also utilizes a MPSS principle but differs from Illumina in utilizing the detection of newly added nucleotides at single molecule resolution enabled by detection of fluorescent phospholinked nucleotides (Rhoads and Au, 2015). In this platform, a single well contains a synthesis reaction of an enzyme, the DNA template, and labelled nucleotides, of which the addition of a specific nucleotide results in a specific signal. The signal is detected at the bottom of the well using a zero mode wave guide that directs one molecule of template and one molecule of DNA polymerase per well. Signals are detected as the synthesis of each nucleotide occurs, thus is giving this technology the name single molecule real-time (SMRT) sequencing. The addition of nucleotides produces a natural DNA molecule and thus can produce very long reads on average of above 10,000 nucleotides (Rhoads and Au, 2015) with up to 75,000 reads giving 0.75×10^9 of sequencing data. While the super long reads are advantageous especially in genome sequencing applications, the Pac Biosystems platform has also been of use in *de novo* transcriptome assembly of novel transcriptomes in RNA sequence informatics. The instrumentation cost is quite high compared to other platforms so this has been another limitation as well as a higher error rate. However, the ability to produce large reads has made it indispensable for applications such as genome assembly, transcriptome assembly, and sequencing complex genetic samples such as those from metagenomics.

Oxford Nanopore is another single molecule sequencing platform (Jain *et al.*, 2016). The technology depends upon small changes in electrical current when characteristic nucleotides pass through the pores. The small size of the platform, similar to a USB memory stick makes this an attractive technology. A recent version contains 500 nanopores from which single DNA molecules pass at 450 nucleotides per second with a generation of more than 5×10^9 of sequence according to a technical update from the company. While accuracy has been a problem for this platform in the past, technology improvements have increased this parameter dramatically in recent months.

Table 1 shows the comparison of sequencing platforms (Fox *et al.*, 2014; Li *et al.*, 2014b; Mardis, 2017).

Transcriptome Mapping

Microarrays contain spatially addressed genes already identified. NGS platforms require the reads obtained from sequencing to be mapped onto a transcriptome if one exists, and to produce a *de novo* transcriptome if it does not. In the former case mapping is typically performed by alignment of the read to a sequence from the transcriptome and then assignment of the read to a particular gene (Mortazavi *et al.*, 2008). In the latter, reads are aligned with each other to obtain continuous sequences (contigs) to generate an assembly, and then assigned to that particular contig (Martin and Wang, 2011). While mapping is intuitively straightforward, the large number of reads and large size of the transcriptome require efficient algorithms to improve upon the computational task of mapping. One algorithm, the Burrows-Wheeler transform (BWT), converts the transcriptome sequences into blocks, sorts these, and because of the many repeats of sequences in the transcriptome, makes it more efficient to search through rather than going nucleotide to nucleotide through the transcriptome. Another algorithm to align reads is to use a hash table, which is simply a table of possible short nucleotide sequences that uses a hash function to compute their locations. Finally, de Bruijn graphs are used since a transcript might have many alternative exons and introns and these need to be considered in the alignment.

In Table 2, different tools which align reads as un-spliced or spliced are shown.

Table 1 Comparison of sequencing platforms

	<i>Microarrays</i>	<i>Illumina</i>	<i>Ion Torrent</i>	<i>Pacific biosystems</i>	<i>Oxford nanopore</i>
Chemistry	Hybridization	MPSS	Hydrogen ion	SMRT	SMRT
Read lengths	N/A	50–300 bp	200–600 bp	250 bp to 40 kb	– 150 kb
Read modalities	N/A	Single, paired end	Single, paired end	Single	1D or 2D reads
Throughput	10–100 MB	7.5–300 Gb	1.5–4.5 Gb	500 Mb to 1 Gb	10–20 Gb
Accuracy		100.00%	99.99%	99.99%	99.96%

Note: Columns indicate different sequencing platforms.

Rows indicate common features of platforms. Chemistry provides technical differences of each platform. Read Lengths measures the input read size. Read Modalities provide the type of read each platform can generate. Throughput estimates the amount of data that is processed by each platform. Accuracy indicates the accuracy of reads generated by the platform. Abbreviations: bp, basepair; Gb, gigabyte; kb, kilobase; MPSS, massively parallel sequencing by synthesis; MB, megabyte; SMRT, single molecule real-time.

Table 2 Aligner and *de novo* assembler

Tools	Alignment type	Read length	Algorithm	System	Link
SOAP	Un-spliced	Short	BWT-based	Linux/Unix/MAC OS	http://soap.genomics.org.cn/
Bowtie	Un-spliced	Short	BWT-based	Linux/Unix/MAC OS	http://bowtie-bio.sourceforge.net/
Bowtie2	Un-spliced	Long	BWT-based	Linux/Unix/MAC OS	http://bowtie-bio.sourceforge.net/bowtie2
BWA	Un-spliced	Short/Long	BWT-based	Linux/Unix/MAC OS	http://bio-bwa.sourceforge.net/
TopHat	Spliced	Short/Long	BWT-based	Linux/Unix/MAC OS	https://ccb.jhu.edu/software/tophat
HISAT	Spliced	Short/Long	BWT-based	Linux/Unix/MAC OS	http://ccb.jhu.edu/software/hisat2
MAQ	Un-spliced	Short	Hash tables	Linux/Unix/MAC OS/Windows	http://maq.sourceforge.net/
PerM	Un-spliced	Short/Long	Hash tables	Linux/Unix/MAC OS	https://code.google.com/archive/p/perm/
SHRIMP	Un-spliced	Short/Long	Hash tables	Linux/Unix/MAC OS	http://compbio.cs.toronto.edu/shrimp/
Trinity	<i>de novo</i>	Long	<i>de Bruijn</i> graph	Linux/Unix/MAC OS	http://trinityrnaseq.github.io
Oases	<i>de novo</i>	Short	<i>de Bruijn</i> graph	Linux/Unix/MAC OS	https://www.ebi.ac.uk/~zerbino/oases/

Note: Rows indicate aligner examples. Columns list the common features of the aligners. The algorithm gives the background algorithm used in the aligner. The System lists the operating system where the aligner works. Link shows the home web page for each aligner.

Mapping values for a data set are provided as a percentage of reads mapped to the transcriptome or genome. More precise values can be given as percentage of read nucleotides mapped to a transcriptome calculated by taking all nucleotides aligned to the transcriptome divided by the number of nucleotides sequenced. These are usually termed % on-target.

Mapping data from NGS platforms generates an alignment file that contains read information and location on transcriptome where it maps. These are sometimes provided as coordinates in the genome where the transcriptome is located that also provides exon and intron data. These files are known as BAM, SAM, WIGGLE files, and have .bam, .sam, .wig extensions (Zhang, 2016). This data is very dense, and an index file can provide a means of searching through the alignment file. Index files have names such as BAI and have .bai extensions.

Transcriptome Output and Normalization

Microarray or NGS sequence data can typically be output as a tab-delimited text file with gene names in rows and samples names in columns (Korpelainen *et al.*, 2014; Laine *et al.*, 2014). Each field contains an abundance value that corresponds to a specific gene and specific sample. For microarrays the value is a fluorescence measurement and for NGS platforms the value is for number of reads. These values need to be “normalized” since fluorescence signals may vary from experiment to experiment in microarrays. Per-chip normalization of microarrays divides all values on the microarray by a number while per-gene normalization divides only a specific gene across different microarrays by a number. Other microarray normalization procedures may convert values to Z-scores, indicating a fluorescence measurement at Z-value, equivalent to one standard deviation from the mean. Thus, a value might be converted to -3.5 meaning its intensity is -3.5 standard deviations from the mean intensity of values on the microarray. Another microarray normalization method converts values to ordinals, so a gene might be the 503rd most highly expressed from 20,000 genes.

For data from NGS platforms, normalization also needs to be performed because while reads are an absolute measurement of transcript abundance, the values for each gene are also a function of the number of overall reads obtained from a sample (Korpelainen *et al.*, 2014). One normalization method is to divide the number of reads for each gene per million reads that map to the transcriptome. This value is called RPM. Values can also take into account the size of a transcript because a transcript 4 kb in size will have 8 times more reads mapping to it than a gene 0.5 kb in size if all other factors are equal. To normalize for transcript size, values are divided by the size of the gene over 1 kb. These values are termed RPKM for reads per kilo bp of the transcript per million mapped reads. Because Illumina can produce paired-end reads by sequencing from both sides of a transcript, the number of reads can be converted into fragments, so that reads from 2 ends of a transcript produce a fragment and these values are normalized as FPKM for fragments per 1 kbp gene size per million mapped reads.

Analysis of Transcriptome Data

Differential gene expression, commonly abbreviated as DG or DGE analysis refers to the analysis and interpretation of differences in abundance of gene transcripts within a transcriptome (Conesa *et al.*, 2016). Lists of genes that differ between 2 sample sets are often provided by RNA-seq data analysis tools, or can be generated manually by statistical testing of data sets. Due to the large number of genes to be tested, (e.g., $> 20,000$ in the human genome), multiple testing correction such as Bonferroni correction is usually applied. Because the number of gene that are differentially expressed between samples may still be high (e.g., > 1000), a method to understand and interpret the meaning of so many gene expression changes is needed. One method to solve this problem is termed “gene set enrichment” or GSE (Hung *et al.*, 2012; Subramanian *et al.*, 2005). In this method, a gene or group of genes that belong to a particular category that are enriched in one sample is compared to another sample. For example, if a breast cancer sample has more genes regulated that are annotated to the “cell cycle genes group” than a control sample. Grouping genes can be performed based on their annotation to a number of sources including the Kyoto Encyclopedia Gene Group (KEGG)

pathway. Genes can also be annotated to a group based on a particular encoded protein motif such as F-box binding domain containing genes. Gene ontology (GO) annotations provide another method to annotate and group genes (Ashburner *et al.*, 2000; Schulze-Kremer, 1997). Ontologies are a structured vocabulary with a hierarchy so that genes that belong in a lower level of the vocabulary also belong to higher levels. For example, genes that are annotated with lower level mitochondrion cristae (GO:0030061), are also annotated with the higher level GO term mitochondrion (GO:0005739). Genes can also belong to multiple groups at the same level. Thus, a differentially expressed gene list may be statistically over-represented in a GO category such as rough ER. There are actually 3 GO categories including molecular function, biological process, and cell component.

A gene co-expression network is a group of genes whose level of expression across different samples and conditions for each sample are similar (Gardner *et al.*, 2003). This network identifies similarly behaving genes from the perspective of abundance and infers a common function that can then be hypothesized to work on the same biological process. A good example of a co-expression network are genes that are coregulated during diauxic shift when changing the energy consumption of yeast from glucose to galactose. During this shift, a new set of enzymes are needed and so genes in the galactose metabolism pathway are activated together (DeRisi *et al.*, 1997). Inverse co-expression can also be useful as a network of co-expressed genes that are inversely related include miRNAs and their targets, where in conditions miRNA levels increase, the mRNA targets should be decreased (Ambros, 2004). DG expression has two measures, magnitude and direction. Co-expressed genes can also be identified by using correlation measures (e.g., Pearson Correlation coefficient) between 2 or more genes.

Transcriptomes can be assembled *de novo*, without other information, or based on a reference sequence. The reference sequence can be a genome sequence from the same organism as the source RNA or a closely related species. Reference sequences can also be closely related transcriptome sequences. The number of reads needed to sequence a transcriptome can be determined by the concept of depth. Given that the human transcriptome accounts for 3% of the nucleotides of the human genome consisting of 3 billion nucleotides, sequencing $0.03 \times 3,000,000,000 = 90$ M nucleotides. Thus, sequencing 90 M would be $1 \times$ depth and on average cover each nucleotide once. However, some genes are more highly expressed than others and some genes are rarely expressed, so even $1000 \times$ depth at 90×10^9 would only provide an even chance of sequencing a transcript that is 1 in a thousand in a cell. Therefore, it is likely that many transcriptome assemblies are not complete. Once assembled, several statistical measures reveal the quality and completeness of the assembly. The number and distribution of contigs indicate whether sufficient sequencing has been performed. Since the human transcriptome contains approximately 20,000 genes, a primate transcriptome might be expected to yield the same number. A smaller number might indicate insufficient coverage while a larger number might indicate contigs that need to be joined. Another measure is N50 size, which indicates the median size of a contig, another is the average size of a contig. Since the average size of a gene in humans is approximately 1.5 kb, values in this range suggest a good transcriptome assembly. Following assembly, novel transcriptomes are annotated usually by alignment with known genes from a closely related species. This is performed either by comparison of gene sequences, or translated protein sequences. In both cases, the annotation provided by the alignment can then be grouped to known functional categories of proteins known to be present in all metazoan species. Examples of these complete protein sets include CEGMA or core genes expected to be present in most metazoan species and BUSCO for benchmarking universal single copy orthologs (Parra *et al.*, 2007; Simao *et al.*, 2015). The inclusion and percentage measurement of genes present in these core gene data sets can give a rough idea of the transcriptome completeness.

RNA-seq data can also identify novel transcripts such as fusion genes (Levin *et al.*, 2009). Fusion genes can be produced based on chromosome rearrangements including translocations, inversions, deletions, and duplications. The junction site for each of the rearrangements can potentially give rise to a Fusion gene. These genes are important as an indicator for cytogenetic events, but also some fusion genes can produce protein products that are functional and their activity may have consequences on the organism where it is expressed (Mitelman *et al.*, 2007). Detecting fusion genes is a complex problem since it may be difficult to tell the difference between an authentic fusion gene and a sequencing artifact. More than 20 software are available for fusion gene detection (Kumar *et al.*, 2016). Generally, these software tools look for reads that begin alignment at one gene and continue at another gene in the genome. Filters are used to decrease the number of false positives, however, it is typical to validate identified fusion genes using experimental laboratory tools such as PCR.

Single nucleotide polymorphisms (SNPs) can be detected from RNA-seq data as well by comparison of the obtained read data to a reference genome. This requires a reference genome with identified SNPs such as those from the 1000 genomes project (Quinn *et al.*, 2013). To differentiate true SNPs from false positives, high coverage of the transcript ($> 10 \times$) is usually required. Another strategy is termed "exome sequencing" where only RNA representing exons are sequenced (Ng *et al.*, 2009). The purpose of this approach is to identify any nucleotide changes, both SNPs and other polymorphisms, in protein coding genes that might account for a specific phenotype (Biesecker, 2010). Sequencing the exome is more efficient by about 100 fold than sequencing the entire genome. In addition, some target enrichment strategies are used to sequence only specific exomes but perhaps in a larger number of samples. This type of sample design fits well sequencing platforms built for speed and simplicity rather than throughput.

RNA-Seq/Immunoprecipitation Methods

RNA sequencing (RNA-seq) has become arguably the most powerful approach for characterizing the abundance and structure of the transcriptome. However, variations in how the RNA is isolated, enriched, and purified have made this approach even more useful. Coupled with the modest cost of sequencing RNA via conversion to a cDNA library, RNA-seq will likely yield huge amounts of important biological data for many years to come (Wang *et al.*, 2009). Below are some common variations of RNA-seq.

Biochemically, the approaches can be broken down into those based on size selection (miRNA-seq), selection based upon immunoprecipitation of RNA-proteins or RNA-protein complexes (e.g., RIP-seq, CLIP-seq, GRO-seq), or selection based on modification of RNA.

Cel-seq: Cell sequencing collects RNAs that are sourced from a single cell and is also known as single cell RNA sequencing or scRNA-seq (Hashimshony *et al.*, 2012; Picelli, 2017; Ziegenhain *et al.*, 2017). Single cells may be isolated in situ or manually from cultures. In some experiments, single cells may also be pooled to gather sufficient RNA for sequencing. Single cells can also be separated from whole animal embryos or complex tissues. Once separated, an emerging technique termed drop-seq joins each individual cell with a unique DNA barcoded bead into a nanoliter droplet using microfluidics. Once in a droplet, a library can be synthesized that contains a unique barcode identifier for each individual cell (Macosko *et al.*, 2015).

CLIP-seq, PAR-CLIP-seq, HITS-CLIP-seq: Cross-linking immunoprecipitation sequencing refers to techniques that physically cross-links RNA to protein, usually via UV light, and subsequently immunoprecipitates the product (Licatalosi *et al.*, 2008). In the PAR-CLIP-seq variation, photo-activatable RNA incorporation into RNA provides a more efficient cross-linking solution (Hafner *et al.*, 2010). HITS-CLIP-seq simply refers to High-throughput sequencing of cross-linked immunoprecipitated RNA products.

GRO-seq: Global Run-On sequencing captures nascently transcribed RNA molecules by selecting for BrUTP nucleotides that are incorporated into the RNA strand during transcription (Danko *et al.*, 2015). This method is generally used to identify active transcriptional regulatory elements.

i-CLIP-seq: Individual nucleotide resolution cross-linking immunoprecipitation sequencing refers to an approach to sequence specific nucleotides (Rosbach *et al.*, 2014; Yao *et al.*, 2014). Access to single nucleotides are provided by first selecting via immunoprecipitation and subsequently by selecting RNAs using sequence specific DNA primers to construct the library for sequencing.

miRNA-seq: microRNA sequencing uses size selection of small RNA molecules to enrich for small noncoding RNAs typically mature miRNAs (Luo, 2012).

Ribo-seq: Ribosome sequencing captures RNAs as they are being translated in the ribosome complex (Calviello and Ohler, 2017). The large size of the ribosome allows this approach to be performed using classical biochemical techniques such as ultracentrifuge gradients. This approach has the same goal as TRAP-seq which is to sequence RNAs actively translated.

RIP-seq: RNA Immunoprecipitation sequencing refers to any technique that uses antibody reactivity to a protein-RNA complex in order select RNAs (Zhao *et al.*, 2010).

SHAPE-seq: This is one of several approaches to identify RNA structure motifs via chemical modifications to the RNA at these motifs. The general principle is to chemically probe RNA structural motifs, perform reverse transcription of the RNA which will terminate at the modified site, and then generate cDNA libraries for RNA-sequencing to uncover the specific RNA sites where the motif was located. SHAPE-seq stands for selective-2'-hydroxyl acylation primer extension and follows these principles (Lucks *et al.*, 2011; Mortimer *et al.*, 2012; Watters and Lucks, 2016).

TN-seq: Transposon insertion sequencing refers to an approach to sequence regions where transposons have inserted into the genome (van Opijnen *et al.*, 2009). Transposon insertion is a molecular biology tool to mutate the genome by insertion of DNA sequences into random genomic loci and then uncover phenotypes resulting from insertional mutagenesis. The method relies on massive parallel sequencing of transposon adjacent areas in order to map insertion sites. It is the most commonly used approach of IN-seq or insertion sequencing. This approach has been used with much success in microorganisms.

TRAP-seq: Translating ribosome affinity purification sequencing is an approach to purify RNAs as they are being translated (Reynoso *et al.*, 2015). The method relies on affinity tagging of a ribosome component (e.g., 80S rRNA) and then utilizing immunoprecipitation to pull down associated RNAs. If successful, this provides transcripts that are part of the translatome.

Fig. 2 shows different RNA transcriptome sequencing methods mapped onto the process of transcription.

Data Integration

Data integration in the context of transcriptional informatics refers to the process of combining RNA structure, abundance, or sequence information with other types of biological information. Other types of information can include DNA sequence, epigenetic marks, protein abundance, protein-protein interaction, or metabolomics data. For example, RNA-seq and ChIP-seq data can be integrated (Angelini and Costa, 2014; Klein and Schafer, 2016). A very common data integration combines transcriptomic and proteomic data (Haider and Pal, 2013). Data integration can also occur between different RNA classes. The scale at which integration is performed is typically at the genome, transcriptome, or proteome level, although sub-genome scale integrations are common especially in pathway or biological process studies.

The purpose of data integration is to gain both a broader and a more precise view of RNA dynamics as it relates to other biologically active molecules and the molecular level (Hawkins *et al.*, 2010). Early data integration efforts were aimed at correlating RNA levels with protein levels to confirm aspects of the central dogma. These basic correlations are still performed and have been extended to relate RNA abundance within RNA classes. For example, negative correlations would be expected of miRNAs with their target mRNAs (Camps *et al.*, 2014). Positive correlations would be expected between mRNAs of transcription factors and their targets. More complex correlations can be found by integrating RNA abundance of genes within a biological pathway with products of that pathway. Data integration has been performed for a large group of physiologic processes such during the cell cycle, cell stress, cell death, and energy metabolism.

Fig. 2 Targets of RNA transcriptome sequencing methods. The image shows biogenesis of miRNAs and mRNAs. Each sequencing method is marked near the target sequences they focus on. GRO-seq (purple) captures nascent transcripts from actively engaged RNA polymerase. RNA-seq (gray) captures mRNAs (in any status, with or without poly-A tail) as input. Ribo-seq and TRAP-seq (blue) captures the mRNAs which are being translated. SHAPE-seq (green) target RNA with a specific structure motif. miRNA-seq aims to capture the small non coding RNA. RIP-seq, CLIP-seq, i-CLIP-seq, CLASH, and other IP methods (red) aim to sequence RNA bound to RNA-binding proteins (RBPs).

At the whole transcriptome level the integration of abundance data, so called expression RNA or eRNA data with other data has proven to be a powerful tool to identify both important genes in disease and physiological processes. For example, integrating eRNA (RNA abundance data) with SNP data from a single tissue of an individual, using a large population, has made it possible to identify specific DNA sequence variations that influence the expression levels of specific genes or sets of genes including both mRNAs and miRNAs (Lappalainen *et al.*, 2013). These SNPs that influence RNA expression levels have been termed eQTLs for expression quantitative trait loci. Such a strategy has also been used to integrate transcriptomic data with metabolomics data in order to identify genes whose expression levels correlate with the abundance of biologically active small molecules in human blood (Bartel *et al.*, 2015).

Although there have been many exceptionally performed integration studies, data integration in the transcriptomic field remains challenging. One bottleneck is that the biological sources of material should be the same and this is not always possible. DNA from cells is relatively stable and can be isolated thousands of years after the organism has died, however, RNA and protein are extremely labile. Another problem is that for genome scale statistics to be performed, the number of samples needed for sufficient power is large. Finally, for reasons still yet to be understood, data do not always correlate as expected on the genome, transcriptome, and protein level. While this complexity is frustrating, it also presents an opportunity to better understand the relationship between all of these molecules in living systems.

Visualization

The RNA research community is currently experiencing the challenge of rapid growth in volume, variety, and velocity of big data. A key step in understanding and learning from RNA structure, transcriptome expression, RNA-RNA interactions, and other RNA properties is visualization (Shabash and Wiese, 2017). An advanced visualization figure is worth a thousand words.

Visualization of RNA is a critical element in interpreting the structure and function of RNA molecules. At its best, visualization provides a means to analyze and interpret RNA data. As the function of RNA depends on its primary sequence, the structure in 2D

and 3D provides insight into its putative function as well as possible mechanism. Most visualization programs provide 2D views of RNA based on thermodynamic considerations although other factors such as base pairing probabilities are also considered. More recently, chemical probing has been used to determine structures (Siegfried *et al.*, 2014). RNA visualization tools are also becoming more sophisticated as required by the discovery of long noncoding RNAs which also function via their secondary structures but may be several kb in length compared to classical tRNAs which are at least 10 times smaller.

Visualization of transcriptome assemblies, alignments, expression, variations and annotations is an efficient way to reveal the unknown. Visualization of transcriptome data can be obtained in various viewers and portals which plot the abundances of transcripts versus different conditions or samples. The most common and simple way to visualize transcriptome expression data is as a heat map with rows representing genes and columns representing conditions. Integrated viewers can provide sequence, structure, function, and abundance visualization within a single tool (Thorvaldsdottir *et al.*, 2013). These views can also integrate genomic information with transcriptomic data.

Visualization of interactions as a network is one way of coping with such data complexity. Since the RNA information for a single gene is related to the information about others, for example, by being co-expressed in cells, or co-regulated by inducers, RNA networks provide an efficient way to visualize the relationships between different RNA molecules. One example is a ceRNA network where miRNAs are connected to mRNAs, lncRNAs, and circRNAs (Salmena *et al.*, 2011). These networks permit discovery of new knowledge and allows inference to form conclusions. Hubs in these networks can help to identify central RNA molecules in a biological process or specific disease.

Artificial Intelligence Approaches

Artificial intelligence (A.I.) is generally defined as the property of machines that mimic human intelligence as characterized by behaviours such as cognitive ability, memory, learning, and decision making. It is an exploding field that encompasses many applied fields including language translation, self-driving cars, and game playing. The success of A.I. techniques in industry fields, has aroused a great deal of interest among biologists. Modern A.I., such as deep learning, promises to take advantage of large data sets for finding hidden structure within them, and for making accurate predictions (LeCun *et al.*, 2015). In the context of transcriptional informatics, a branch of A.I. that has found abundant applications is machine learning. Given a training set of data, A.I. algorithms can determine characteristics or properties of the data and based on this knowledge can act on new input data in various intelligent ways such as classification, prediction, and performing calculations (Swan *et al.*, 2015). Such an approach has been used, for example, to identify biomarkers during disease processes. Machine learning applied to transcription informatics includes neural network algorithms to cluster gene expression data from microarrays, predict mRNA targets from miRNA sequences, fold RNA molecules to secondary structures, and identify and correct biases in RNA-seq data (Heikkinen *et al.*, 2011; Toronen *et al.*, 1999). The common characteristic of these problems in RNA biology is that the precise answer is not clear, although there may be some basic principles to be followed. A large training set exists that can be used to identify and weigh specific parameters that will provide the best possible way to solve the problem given that set of information. Cross validation via external sample data sets or independent experimental validation have been used to provide confidence and to verify answers provided by A.I.

Tools and Resources: Databases, Browsers, and Portals

Recent advances in NGS technologies have created unprecedented amounts of big RNA-seq data sets for study, and many software and database resources are being developed for assisting biology researchers to deal with RNA-seq datasets. Many analysis tools have been developed for different study purposes, by diverse implementation techniques and in distinct interfaces. Many bioinformatics tools have been implemented to analyze RNA-seq data, including tools for preprocessing, read alignment, and other downstream analysis tools such as transcriptome quantification, differential expression analysis, peak finding etc. **Fig. 3** shows the basic steps of RNA-seq analysis and example tools involved in each step.

Tools for RNA-seq analysis include standalone software, databases, and web services. The Sequence Read Archive (SRA) is a database portal which collects many RNA-seq raw data sets and makes them publically available for new discoveries, meta-analysis, and reanalysis (O'Sullivan *et al.*, 2017). The most basic and essential part of RNA-seq is mapping reads to the reference genome. MAQ, BWA, Bowtie, SOAP, STAR, etc. are the commonly used aligners and many of them are command line tools running on the Linux system (Bao *et al.*, 2011). Visualization tools help view the alignment, such as the stand-alone software Integrative Genomics Viewer (IGV) or the web-based tools Genome Browser (Pavlopoulos *et al.*, 2015). While the basic tools are limited to a single function like a piece from a LEGO building block, workflow tools (including integrated analysis tools, workflow management systems) aim to combine and efficiently use separate tools and resources. Galaxy and Chipster are two outstanding representatives of a workflow management system where the user can choose certain tools from a large tools collection to make their own custom workflow through a web-based user friendly interface (Poplawski *et al.*, 2016). Workflow tools are typically hard to configure, but easy to use. Take Chipster as an example. It starts from a java web start desktop client. The user then chooses the tools from a large catalogue and selects the input, sets parameters, uploads raw data files and clicks a button to submit jobs. The whole process is program-free and combined with advanced visualization can more easily become available to the broader community. Also workflow tools can be deployed in a private cloud or local high performance cluster (HPC) for advanced users.

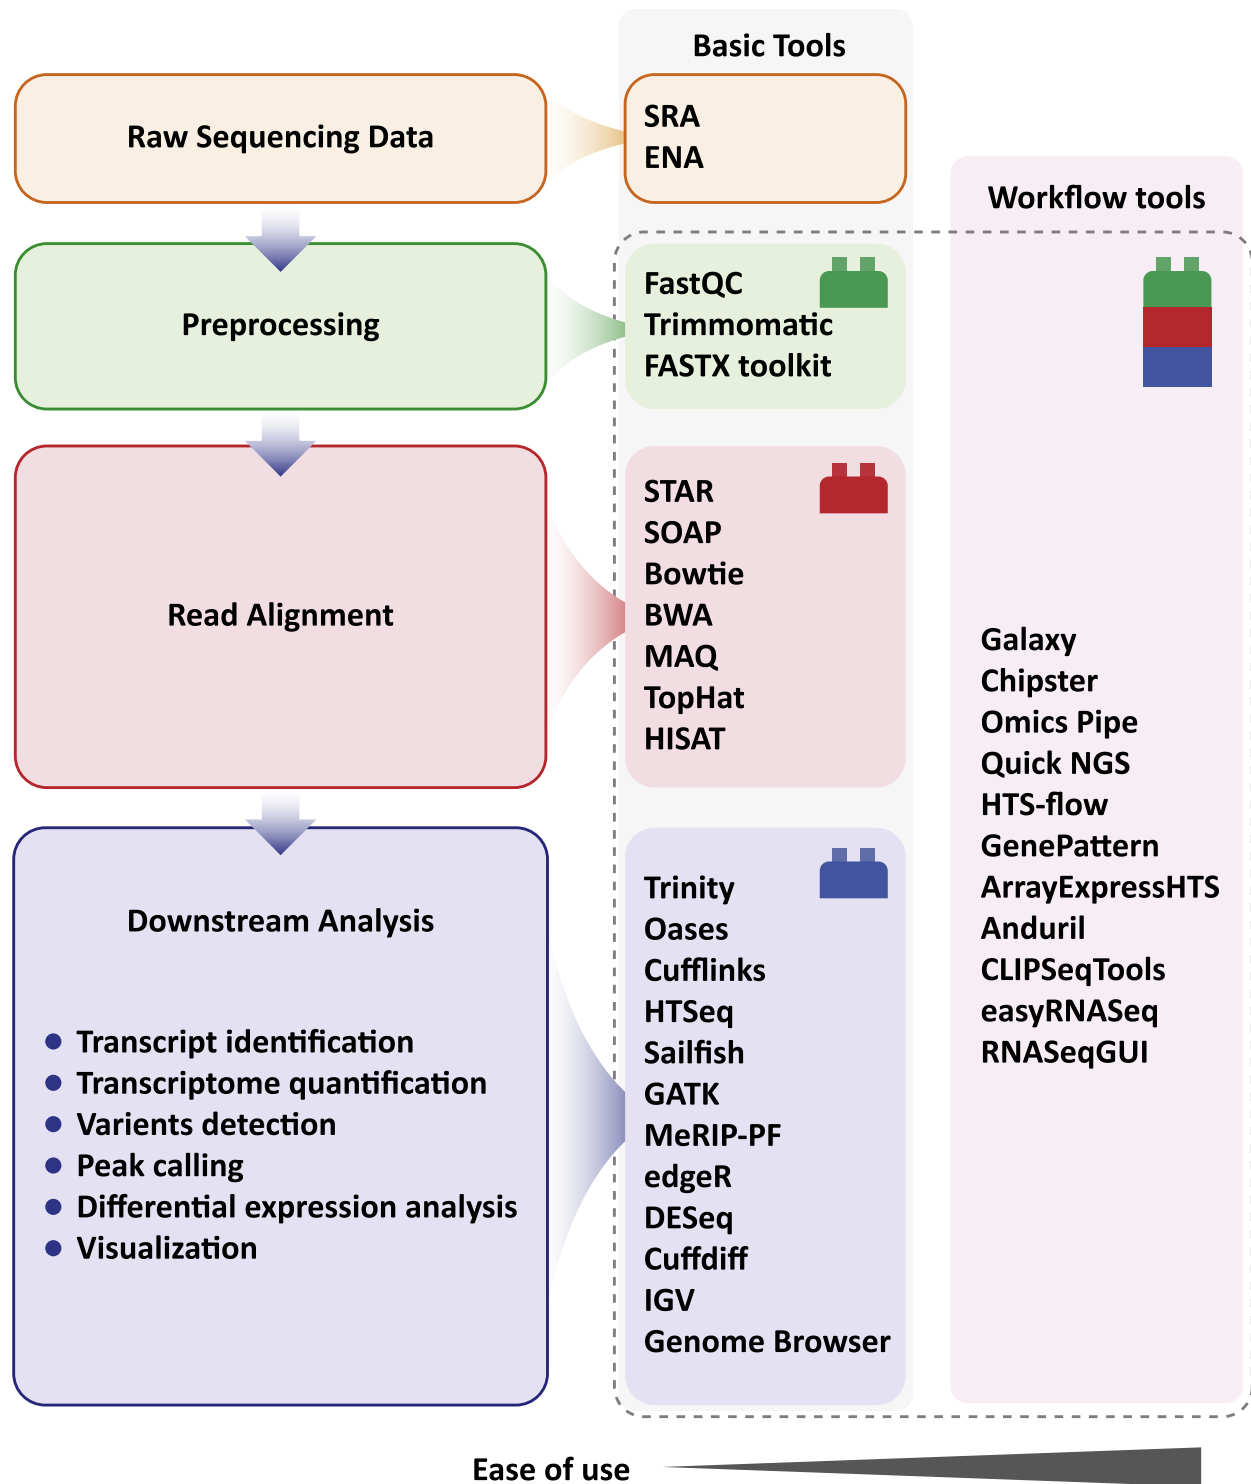

Fig. 3 Basic workflow of RNA-seq analysis and available tools. The left is the basic workflow for NGS data analysis, including raw sequence data (orange), preprocessing (green), read alignment (red), and other downstream analyses (blue). Names of tools are provided that correspond to specific sections in the workflow. In the figure, we only list a small portion of existing tools for each analysis step. All-in-one integrated analysis workflow tools are also being developed to utilize a variety of tools and these are indicated with multiple colored blocks.

Many tools have a unique feature for a particular application. Workflows may report different results although they have the same analysis goals. These differences may be caused by a different combination of tools in the workflow, or different parameter settings. Large scale tools are available, but no gold standard for how to integrate them exists. Due to bandwidth, network speed,

storage space and other hardware limitations, it is still difficult to analyze an RNA-seq dataset through internet based workflow tools only. Even Galaxy, a popular workflow tool, can only handle a small sized data set. To perform batch analysis, a large and private data set still needs to run on the workflow locally and rely on large computational resources. Although tools are diverse and extremely fragmented, biologists or bioinformaticians can nearly always find handy tools for their own study.

Summary

The RNA field is broad. From structure to function to sequence, the vastness from which biological systems have modified, edited, extended, and synthesized RNA is truly astounding. Scientists are only now beginning to grasp the depths and variety of RNAs in living systems. Major advancements in engineering, computer science, and biological understanding have greatly aided RNA transcriptomics as a field of study and research. Indeed, the tailwind created by the decreased cost of sequencing RNA, storing, and processing the information has expanded the field enormously. Yet there is still a sense that hardware and software is just keeping up with the demands of the field. Finally, while many important discoveries in RNA biology have only been reported recently (e.g., RNA interference, long noncoding RNAs, circular RNAs) we wonder what new discoveries await us. As one would think of an encyclopedia as a reference work of factual information, we look forward to when we can add more details at greater accuracy and in abundance. Indeed, it is likely that next iterations of this encyclopedia will change over the years in large and unexpected ways. Such is life in an RNA world.

Acknowledgments

We thank members of the Wong Laboratory Dr. Merja Lakso, Yang Yang, Menglei Zhang, and Changliang Wang for critical reading and discussion. This manuscript would not be possible without the guidance and enthusiasm of Dr. Eija Korpelainen. This work was supported by a grant from the University of Macau MYRG-2016-00101-FHS.

Introduction

Since the late 90s, the rapid development of the high-throughput omics technologies has led to a generation of the available transcriptomic data that demands effective solutions for organization, storage and further progress of new analysis tools. Database platforms have therefore been extensively developed to address these needs. Data repositories containing both curated and user-submitted entries are vital sources of knowledge for both researchers across various fields such as bioinformaticians, biologists, and clinicians for data analysis and for elucidating numerous processes within a disease or its development stages. As the development of omics technologies and bioinformatics continues, possibilities for data integration would allow inferring many more conclusions that could be crucial for a variety of problems arising from fundamental researches or practical applications in biomedicine and agriculture. The development and appearance of transcriptomic databases, in particular, can be useful to prevent pharmacological disease and even increase yield by determination of biomarkers or potential effector genes in cancer and plant pathogens, as well as identification of favorable alleles from the crop landraces.

We have conducted a Pubmed publications analysis for the occurrences of the terms “database” and “transcriptome” in both the title and the abstract of a publication to infer the “chronology” of this development. Thus, the first occurrence of the term “database” in a publication’s title is dated as early as 1974; “transcriptome” made the first appearance much later in 1998 and both terms were used together in both the title and the abstract of a publication for the first time in 1999.

As Fig. 1 illustrates, a log10 scale increase trend in the terms’ use showed a corresponding growth of interest in the omics research, however, even nowadays, the occurrences of both “transcriptome” and “database” terms in the titles and abstract reflect, to the best of our knowledge, an absence of publications that could provide comprehensive overviews of the currently available transcriptomic resources. Thus, the aim of this review is to provide an overview of the current state of transcriptomic databases as broadly divided into the categories of human, animal and plant sources. A short summary of the database types will be provided for each category.

Human Transcriptome Databases

The human databases are mostly disease-specific sources with a particular focus on cancer data in addition to tissue-, interaction- and development-specific data platforms. Other human data sources include circRNA/ncRNA repositories, platforms containing raw full transcriptome data with the SNP information, the sources containing transcriptional signatures from selected experiments in the GEO databases, as well as functional databases.

Fig. 1 Appearances of the terms “database” and “transcriptome” in the titles and abstracts of the available PubMed publications (as of March 2018); the number of publications is presented on a log10 scale.

Multiple Cancer Sources, Single Cancer-Specific Sources and an RNA-Specific Cancer Database

The largest source of cancer data estimated at 2.5 petabytes is represented by TCGA (Chang *et al.*, 2013) (The Cancer Genome Atlas). TCGA is a result of a concentrated effort between the National Cancer Institute (NCI) and the National Human Genome Research Institute (NHGRI) with 20 collaborating institutions to present the range of genetic changes and comparison between the samples and with the normal tissue profiles for 23 most common types of cancer in addition to 10 rare cancers. TCGA provides information on molecular, DNA, protein and epigenetic aberrations resulting in a better understanding of cancer subtypes and higher precision of treatment options as the types of cancer chosen for study have a poor prognosis and result in a major detrimental public health impact (e.g., pancreatic ductal adenocarcinoma, acute myeloid leukemia, cutaneous melanoma). As of now, the data is compiled from 11,000 patients and includes whole genome and exome profiles, mRNA/microRNA sequences, copy number and methylation profiles as well as protein activation status information. Clinical data and data regarding the sample (e.g., weight) are available for some of the sample entries.

Another major data source which contains cancer data in addition GEO-NCBI (the Gene Expression Omnibus) (Barrett *et al.*, 2012) is a public submission data repository containing high-throughput sequencing and microarray data that was created and is under maintenance of the National Center for Biotechnology Information (NCBI). The submitted data comes from the scientific communities worldwide resulting in MIAME (Minimum Information About a Microarray Experiment)-compliant data entries representing more than 1 min samples and 1600 organisms (humans, animals, plants, bacteria and fungi) with links to 20,000 related publications, 90% of the data coming from gene expression studies characterizing such processes as development, metabolism and disease. The database is a user-friendly archival resource that has a number of useful options such as “similar studies” and “find pathways” (i.e., gene mapping to a list of frequency weighted pathways in NCBI BioSystems database) search options, repository browser and GEO2R web app which allows to perform differential gene expression analysis on more than 90% of GEO entries. The data is divided into 3 categories of Platform (array/sequencer description), Sample (biological materials/experimental protocol descriptions) and Series (a link between a group of related Sample and the point of the whole study). GEO DataSet compiles the comparable Samples into a consistently processed format that is divided into categories based on experimental variables and has a description of the study. Thus, a search for term “cancer” in GEO Datasets (all fields) results in 646,300 entries with 1272 DataSets and 616,885 Samples (as of March 2018). The cancer information is available for both humans, animals (e.g., mouse and zebrafish) and constructs (e.g., studies on protein expression data from using viral constructs and cancer xenografts); a number of DataSets contain expression information on metastatic cancers.

Another database which includes transcriptome information on multiple types of cancer is BioXpress (Wan *et al.*, 2015). BioXpress is a database of gene expression and cancer association. It includes gene expression data from 64 cancer types from 6361 patients. It also provides 17,469 genes with 9513 of them showing differential gene expression between normal and tumor samples. To facilitate pan-cancer analysis, all cancer types are mapped to Disease Ontology terms. BioXpress database includes mappings of expression levels to genes using RNA-seq data extracted from The Cancer Genome Atlas, International Cancer Genome Consortium, Expression Atlas. Expression levels are also obtained from publications of large-scale studies.

CoReCG, HNdb and curatedOvarianData databases are cancer-specific and discussed below. CoReCG database contains a comprehensive review of previous studies on colon-rectal cancer (Agarwal *et al.*, 2016). They collected the information about the genes associated with colon-rectal cancer from high-quality published literature and organized this data into the CoReCG database. CoReCG contains 2056 cancer genes annotation involved in distinct stages of colon-rectal cancer. CoReCG database contains comprehensive information about genes such as locations in chromosomes, homology, ontology, SNP information, genomic coordinates, mRNA, information about proteins, etc.

The Head and Neck (HNdb) database (Henrique *et al.*, 2016) was created to provide a comprehensive resource of the Head and Neck squamous cell carcinoma genes (HNSCC) and associated proteins. The retrieved previously performed studies from PubMed database and developed a methodology for literature mining to identify genes associated with HNSCC. The information about the gene can be searched by the name of the gene or its associated protein, by gene symbol, aliases. Also, the information about chromosome regions and gene associated with HNSCC can also be obtained. The database also includes the information about gene ontologies, metabolic pathways and links for comparison of the expression features in normal tissues. The protein page includes the proteins' 3D structures, posttranslational modifications, metabolite and protein-protein interaction as well as drug targets.

Transcriptomic database of ovarian cancer (Ganzfried *et al.*, 2013) was implemented as the *curatedOvarianData* Bioconductor package in R. It contains microarray data of 2970 patients from 23 studies with curated and documented clinical metadata. They pre-processed available Affymetrix microarray data by the same normalization algorithm. For the Affymetrix U133A and U133 Plus 2.0, they used fRMA normalizing algorithm. Then, the analysis of expression levels of *CXCL12* was performed in all primary tumor samples included in the database. The samples were centered by their means and divided by their standard deviation to ensure that expression levels are compared on the same scale. They confirmed the hypothesis that poor outcome in 2108 patients from 13 independent studies with different stages and histologies was associated with upregulation of *CXCL12*. They emphasized the importance of biomarker validation in sufficiently large collections of data.

Cancer RNA-seq Nexus (Li *et al.*, 2016) is the first publicly available RNA-seq database that contains comprehensive data analyses and archives for transcript profiles of coding sequences, long non-coding RNA (lncRNA), coexpression networks, visualization of differential gene expression profiles and phenotype-based data searching and organization. It contains in total 54 human cancer RNA-seq datasets for 11,030 samples and 326 phenotype-specific subsets where each subset represents the group of samples under specific cancer type and stage conditions. mRNA-lncRNA coexpression networks can be visualized, compared and

analyzed for different pairs of phenotype-specific subsets. Coding transcript/lnc expression profiles can also be visualized. Its functionality and user-friendly interface makes Cancer RNA-seq Nexus serve as a handful tool for personalized medicine research.

Other Disease-Specific Sources: Kidney Diseases, Parkinson's, Inner Ear Diseases, Prion Disease, Complex Diseases

Renal Gene Expression Database (RGED) was developed in [Zhang et al. \(2014\)](#) to provide researchers with an access to gene expression profiles of various kidney diseases. RGED includes profiles obtained from renal cell lines, human kidney tissues and murine model kidneys. They searched for gene expression profiling experiments from NCBI and selected a total of 88 studies that published between 2004 and 2014. The platforms are varying across different studies but most of them used Affymetrix, Inc., Illumina, Inc. and Agilent Technologies, Inc. RGED contains profiles of kidney carcinoma, acute kidney injury, autosomal dominant polycystic kidney disease, IgA nephropathy, chronic kidney disease. RGED release 1.0 has a collection of 5354 samples which include cell lines, human tissues and model animals. Previously created databases for kidney research contains only genes or genomic loci in a human which may not be sufficient for a comprehensive study of kidney diseases. RGED allows exploration of gene profiles, relationships between genes of interests, identification of biomarkers and drug targets in different kidney diseases.

The first queryable database ParkDB for gene expression in Parkinson disease was developed in [Taccioli et al. \(2011\)](#). ParkDB has three main functions. The first is to collect all microarray data related to Parkinson disease from publicly available sources such as Array express, Gene Expression Omnibus (GEO) and Stanford microarray database. The second is to provide information about differentially expressed genes across different tissues, treatments and species. The third is to provide information about statistical analysis of microarray data to provide users with the comparison between different experiments.

Shared Harvard Inner Ear Laboratory Database (SHIELD) was developed by [Shen et al. \(2015\)](#). SHIELD is an integrated resource of genomic, transcriptomic and proteomic information of the inner ear. It contains five datasets that are combined into a relational database and provides experimental data and annotations. They derived annotations from public databases and publications. Annotations include gene symbols, gene name, synonyms, human and mouse chromosome cytogenetic banding, genomic coordinations, RefSeq RNA, Ensembl, ontology, etc. Five datasets represent different developmental stages of the variety of model organism species and different cell types. Most commonly used platforms are RNAseq (3*DGE and full-length mRNA), Microarray (GeneChip Mouse Gene 2.0 ST and MOE430) and mass spectrometry.

Prion Disease Database (PDDDB) ([Gehlenborg et al., 2009](#)) developed by is a comprehensive transcriptomic database of mouse prion disease, which provides primary experimentally obtained data. The PDDDB contains mRNA measurements across the time spanning the interval from prion inoculation through the onset of clinical signs in eight mouse strain-prion strain combinations.

dbPTB database was created by [Uzun et al. \(2012\)](#) to facilitate the identification of genetic variants associated with complex diseases. The database combines information about genes, their SNPs, genetic variations and various pathways involved in the preterm birth. They searched publicly available databases and publications that describe genome- and transcriptome-wide studies. Genes, which expression levels were increased or decreased in the association with preterm delivery were included in the database.

Tissue-, Process- and Interaction-Specific Sources: Human Oral Microbiome, Human Brain Transcriptome, Human Ageing, Neurological Ageing, Genotype-Tissue and Genotype-Phenotype Interactions

Human Oral Microbiome Database (HOMD) ([Chen et al., 2010](#)) provides datasets for more than 600 prokaryote species of a human oral cavity. HOMD provides both taxonomic and genomic types of information. Each species was given a unique Human Oral Taxon (HOT) number based on the 16S rRNA gene sequence analysis. Each HOT contains genomic, clinical, phenotypic, phylogenetic and bibliographic information for each taxon. Gene sequences can be matched to full-length 16s rRNA reference dataset by using BLAST tool. HOMD can serve as a model for microbiome database of gut, skin and human body cavities.

The HBT (Human Brain Transcriptome) database ([Johnson et al., 2009](#)) is a public database for transcriptome data and the associated metadata for the developing and adult brain, from data on males and females of different ethnicities, from different brain regions and neocortical areas. The database is built upon the results of whole-genome, exon-level expression analysis of 16 brain regions, generated using Affymetrix GeneChip Human Exon 1.0 ST Arrays. Over 1340 tissue samples from both hemispheres of postmortem human brains were analyzed. The authors applied ANOVA for differential expression analysis and unsupervised hierarchical co-clustering for analyzing brain regions with respect to their transcriptional profiles. The online database enables searching for individual genes and assessing their temporal activity in an age-intensity graph, or searching for the most active genes with regard to their spatial (by brain structure) and temporal (by start and end period) activity.

GenAge, a database of genes potentially associated with human ageing ([Tacutu et al., 2013](#)), was developed as a part of The Human Ageing Genomic Resources (HAGR) framework. GenAge is a publicly available, continuously curated database containing a comprehensive list of genes potentially associated with ageing in humans and model organisms, as well as a list of differentially expressed genes in mammals, including humans, from a meta-analysis of microarray studies. The manually-curated list of human genes in GenAge is 288, annotated with respect to their role in the human ageing process as a whole, as a result of analysis of more than 2200 references. In addition, it includes over 1700 genes associated with longevity in model organisms, which are based on experimentally validated results from the multitude of studies, such as overexpression of certain transcripts or RNA interference with age. Each entry in the database a description of its main functions and its relation to the ageing process, as well as the reason for inclusion into the database.

Brain transcriptome studies on gene dysregulation in Alzheimer's disease (AD) and closely related processes such as ageing and neurological disorders were collected and curated in AlzBase database (Bai *et al.*, 2016). Aside from gene dysregulation in AD, it includes information on correlation of gene dysregulation with severity of AD, functional and regulatory annotations, and a network of the corresponding gene-gene interactions, built via WGCNA. It includes a total of 14,145 dysregulated genes. For gene annotations, eQTL experiments (11,055), in situ hybridization experiments (1167), and GWAS experiments (12,287) were used. The authors constructed a gene coexpression network using several large datasets on brain transcriptome taken from GEO, which covered AD-associated data on several brain regions and peripheral blood, and four stages of progression of the disease. For the selection of differentially expressed genes, the RankProd algorithm ($p < 0.05$) was used. To further group the most significant genes (277), the authors used hierarchical clustering and grouped them into 11 clusters based on the temporal pattern of gene expression.

The Genotype-Tissue Expression (GTEx) database was created as part of GTEx project which aimed at establishing a data resource for studying the relationship between genetic variation and gene expression in human tissues (GTEx Consortium, 2017). The GTEx represents the results of high-throughput sequencing and microarray analysis used for eQTL analysis from samples (7051) of 44 different tissue types from 449 donors. The authors compared Spearman's similarity between various tissues for cis- and trans- eQTLs and used agglomerative hierarchical clustering to group the tissues that share any given eQTL. The GTEx's web portal enables searching for genes by Gene or SNP Id and outputs a visualization of its median expression level across all samples for each tissue.

dbGaP, the database of Genotypes and Phenotypes, was developed for storing and distributing the data from studies of genotype-phenotype interaction in humans (Mailman *et al.*, 2007). It is a large NCBI-sponsored public repository that assigns unique identifiers to studies and datasets. The main objective of the project is to store, collect and distribute phenotype data that can be associated with other data types, such as sequence-derived genotypes and haplotypes, gene expression data, proteomic, metabolomic, and epigenetic data. Currently, the main focus of the GWAS studies covered in dbGaP is microarray data. dbGaP has integration with Sequence Read Archive (SRA), and thus the sequences for the queried genes can be downloaded from the NCBI web portal. Aside from that, users can view the association results in Genome Browser's chromosomal viewer, where loci with the smallest p-value are color-coded, and in the sequencing view, users can see the corresponding gene/ transcript/protein annotations.

Other Tools and Sources: Circular RNA/Small Non-Coding RNA Databases, Raw Read Archives, a Transcriptome Browser and a Human Transcriptome Functional Annotation Source

CircNet is a database for circular RNAs which is the type of regulatory noncoding RNA (Liu *et al.*, 2016). The expression of circRNAs was identified by using transcriptome sequencing datasets in 464 RNA-seq samples. CircNet provides an access novel circRNAs, integrated miRNA-target networks, expression profiles, genomic annotations and sequences of circRNA isoforms. It also displays the regulation between circRNAs, miRNAs, and genes by generating the integrated regulatory network. By using the search box, users can find the gene-miRNA-circRNA regulatory network of particular genes. CircNet allows studying circRNA tissue-specific functions and correlation to diseases due to its expression profile and accessibility.

Human genome data generated from next-generation sequencing and high-resolution comparative genomic hybridization array were collected into the Total Integrated Archive of short-Read and Array (TIARA) database (Hong *et al.*, 2013). TIARA provides an access for variant information and raw data for 16 sequenced transcriptomes, 13 sequenced whole genomes and 33 high-resolution array assays (for September 2012). Genomic variants data includes a total of approximately 9.56 million SNPs, where 23,025 constitute non-synonymous SNPs and approximately 1.19 million indels. The abundance of genomic variants data makes it a useful resource for personalized genomics studies. Genome browser allows the matching of whole-genome sequence with transcriptome sequencing data. Also, the levels of gene expression can be observed with allele-specific quantification.

For storing next-generation sequence data (Leinonen *et al.*, 2011), the Sequence Read Archive (SRA), which serves as NIH's primary archive of high-throughput sequencing data, was created. The SRA stores raw sequencing data and alignment information through such high-throughput sequencing platforms as Roche 454, Illumina Genome Analyzer, SOLiD™, Helicos HeliScope™, Complete Genomics, and SMRT™. The SRA archives raw oversampling NGS data with EMBL and DDBJ, as well as the data from human clinical samples. The database enables users searching for genes of interest via metadata in the query request, as well as performing a sequence-based search using BLAST.

TranscriptomeBrowser (TBrowser) (Lopez *et al.*, 2008) was created for hosting a large integrated database of transcriptional signatures extracted from more than 1400 (currently ~4000) experiments stored in the GEO database. The authors used a modified version of the Markov Clustering algorithm – DBF-MCL, to systematically extract clusters of co-regulated genes, which allowed to define over 18,000 transcriptional signatures (currently around ~40,000). The authors tested established transcriptional signatures for functional enrichment using DAVID knowledgebase, and over-representation of functional terms was found in a large proportion (84%) of these transcriptional signatures. The TBrowser enables searching by GeneID and annotation, and supports Boolean operators.

The GENCODE is an online database developed as a part of the ENCODE (Encyclopedia of DNA Elements) project, which contains functional annotations for 20,687 protein-coding genes, 9640 long non-coding RNA loci for 15,512 transcripts, and 33,977 coding transcripts not represented in RefSeq and UCSC (Harrow *et al.*, 2012). The gene annotations are derived from a combination of manual curation and automatic gene annotation from Ensembl, different computational analysis techniques (PhyloCSF, APRIS annotation pipeline), and targeted experiments. GENCODE contains a comprehensive and manually annotated set of pseudogenes, in addition to the sets of protein-coding and non-coding genes. The authors also used transcriptome

sequencing data facilitated by high-depth RNA sequencing for a very detailed overview of alternative splicing. The web portal of GENCODE enables searching by ENS id, ENS gene id, and gene name (for a corresponding BioDalliance genome visualization), as well as downloading all the relevant GTF/GFF3 datasets, FASTA datasets, and the metadata files.

Database of small human noncoding RNA (DASHR) is the most comprehensive database on human sncRNA genes and mature sncRNA products (Leung *et al.*, 2016). DASHR integrates over 180 smRNA smRNA-seq datasets over 2.5 billion reads and annotation data from various publicly available sources. DASHR contains 7641 sncRNA gene records, and 9703 mature sncRNA product records, corresponding to ~48000 genomic loci. Among the sncRNA genes, 82% are expressed in one or more tissues. As such, 6301 annotated sncRNA genes can be queried in DASHR. DASHR has an intuitive web interface that allows users to search by full name, partial name or ID of sncRNA, compare expression levels in various human tissues, locate RNA loci overlapping with the given genomic coordinates using h19 transcript annotation as a reference, or query by raw RNA sequence. It also provides a summary of annotation and expression information, with an expression heatmap, an expression profile across tissues, and a genome browser for mapped sequences.

Animal Transcriptome Databases

Animal transcriptome databases are mainly represented by the data sources containing the genome and transcriptome sequencing/RNASeq/expression/functional annotation information on the model and mammalian organisms such as *Xenopus*, *Mus musculus*, *Rattus norvegicus* and *Sus scrofa*, combining sequencing and expression data. *M. musculus*-focused databases are represented by data repositories on embryo and brain development as well ageing, reflecting the fact that mouse is a model organism for most of the crucial mammalian processes as important to human health and development research. Ageing-related databases also include entries from *Caenorhabditis elegans*, *Drosophila melanogaster*, *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* as the organisms are widely used for understanding ageing processes *in vivo*. Arthropods and parasites are also represented by the relevant database source reflecting the importance of the omics data for studies in comparative genomics, evolutionary and developmental biology as well as ecology and plant/human disease management (e.g., rice pest *Chilo suppressalis* and *Leishmania* databases). Another important animal transcriptome database source is a *Ctenopharyngodon idellus* (grass carp) GCGD database; the grass carp is an important farmed fish for the global freshwater aquaculture business. In addition, as mentioned in the previous section, GEO-NCBI also contains a wide range of data from animal sources.

Model and Mammalian Organism Sources

Xenbase is an online database that provides an access to the sequencing data for *Xenopus laevis* and *Xenopus tropicalis* (Karimi *et al.*, 2018). The data were obtained from different resources such as publications and bioinformatics analyses. The database includes genomes for both *X. laevis* and *X. tropicalis*, chromosomal assemblies, annotations, genome segmentation, visualization of RNA-Seq data, protein interaction, gene ontologies, updated ChIP-Seq mapping, etc. Users can use BLAST pages from the main navigator bar and select the genes of interest. They also provide the graphical representation of the genomic and chromosomal structure by using the gene coordinates data.

cSynechococcus sp. PCC 7002 omics studies were combined into the CyanOmics database (Yang *et al.*, 2015). It comprises one genomic dataset, one proteomic dataset and 29 transcriptomic datasets. CyanOmics provides functional annotation for complete genome sequence, transcriptomes under different experimental conditions and proteomic analyses. They also integrated tools for browsing, navigation, sequence alignment and data visualization. The database provides links.

The Mammalian Transcriptomic Database (MTD) was developed by Sheng *et al.* (2017) for characterization and comparative analysis of transcriptome data, and it comprises RNA-seq data from most available tissues of certain mammalian species. Currently, MTD contains RNA-seq data from *Homo sapiens* (83), *Sus scrofa* (27), *Rattus norvegicus* (36) and *Mus musculus* (108). Among the core features of the database is that it allows finding genes based on their neighboring genomic coordinates or joint KEGG pathway, and displays detailed expression information on exons, transcripts, and genes in a genome browser (GBrowse). The MTD enables comparative transcriptomic analysis in both intraspecies and interspecies manner. The database is implemented as a web interface, which provides the following functionalities: Browse (by chromosome, region, or pathway), Search (by gene feature or isoform feature), Analysis (intraspecies and interspecies), and Download (for raw SRA data or gene expression data by tissue/cell line).

Database of Transcriptome in Mouse Embryos (DBTMEE) (Park *et al.*, 2015) was developed for systematic analysis of *mus musculus* fertilization dynamics. DBTMEE is based on ultra-large-scale RNA-seq analysis, with more than 1.5×10^5 oocytes sequenced. The authors also included data from other publicly available resources, such as microarray gene expression data, RNA-seq data prepared by different sequencing protocols and at various cell types and embryonic stages, as well as mass-spectrometry proteomic data, DNA-methylation data and ChIP-seq of histone variants in spermatozoa. The database has a comprehensive web interface, through which the users can identify fertilization-specific genes, assess the impact of histone modifications on early embryo development, and use genetic and epigenetic characteristics to investigate molecular characteristics among totipotent, pluripotent, and differentiated cells. The authors applied hierarchical clustering to categorize the gene expression patterns with respect to mouse embryonic development, and the results of the clustering (with further details and links for each gene within each cluster) are accessible from DBTMEE's front page.

The Brain Transcriptome Database (BrainTx) was developed by Sato *et al.* (2008) as a successor to Cerebellar Development Transcriptome Database (CD-DBT, alternative/former name), an online database centered around transcriptomes related to a cerebellar development of a mouse. The current version of BrainTx represents an integrated online platform for visualization and

analysis of transcriptomes related to various stages and states of the mammalian brain (primarily brain of *mus musculus*, but also includes vast amounts of data on other species). Aside from search by NCBI Gene ID and CD ID, it enables searching for genes and transcription factors via associated keywords, e.g., name of the related gene, name of the associated protein structure or function, or cell function. The online database enables searching for differentially expressed genes during the different stages of brain development, analyze expression patterns with respect to the region (Brain distribution) and tissue distribution pattern (Brain specificity). BrainTx's Gene Ontology Tree Browser includes 6603 genes annotated for their associated biological processes, 5782 genes annotated for their associated cellular components, and 6968 genes annotated for their associated molecular functions.

AGEMAP (Atlas of Gene Expression in Mouse Aging Project) (Zahn *et al.*, 2007) is a gene expression database that catalogs changes in gene expression profiles as a function of age in mice. The authors of the database generated mRNA transcript profiles in mice with respect to changes in age and included 8932 genes in 16 tissues at 4 times during the aging. The authors used hierarchical clustering to categorize the data on age-related transcriptional changes into 3 groups (3 modes of aging for different mouse tissues): neural tissues, vascular tissues, and steroid-responsive group (thymus, gonads), which suggests that different types of tissues have different rates of aging. Certain mice tissues exhibit the strongest transcriptional differences as a function of age, while other mice tissues show little to no difference with age. The database can be downloaded as Z-normalized expression data for each tissue.

GenDR is a database also developed under The Human Ageing Genomic Resources (HAGR) framework (Wuttke *et al.*, 2012). GenDR is the first database that contains consistent gene expression changes induced by dietary restriction, in addition to gene mutations interfering with dietary restriction-mediated lifespan extension. The authors established transcriptional signatures induced by dietary restriction (DR), analyzing differentially expressed genes from microarray data in model organisms (*Caenorhabditis elegans*, *Drosophila melanogaster*, *Mus musculus*, *Saccharomyces cerevisiae*, *Schizosaccharomyces pombe*). For all the model organisms, they assessed the influence of gene expression changes upon DR on the multiple interactomes within an interaction network (using ExprEssence algorithm, analysis of suppressed and stimulated interactions, and DAVID functional enrichment analysis). They identified more than 100 genes that are essential for an effect of dietary restriction to take place (DR-essential genes) in model organisms. The web interface of GenDR enables matching genes with the list of DR-essential genes by Entrez ID, gene symbol or name, or browsing the list of DR-essential genes by species. Finally, it allows comparing the DR-essential genes with their homologs across other species, including *Homo sapiens*.

Arthropod and Parasite Sources

Genomic and transcriptomic database ChiloDB for rice insect *Chilo suppressalis* was developed by Yin *et al.* (2014). The aim of ChiloDB was to provide researchers with access to recent genomic and transcriptomic data to allow comparative genomic studies. They integrated the data with protein-coding genes, microRNAs, piwi-interacting RNAs (piRNAs) and RNA-Seq data. They also provide gene annotations for *Chilo suppressalis*. ChiloDB contains the first version of the *Chilo suppressalis* gene set that includes 10,221 annotated protein-coding genes and 80,479 scaffolds. They identified 82,639 piRNAs with piRNAPredictor software and predicted 262 microRNA genes from small RNA library. They also integrated 37,040 transcripts from midgut transcriptome and 69,977 transcripts from a mixed sample.

Assembled Searchable Giant Arthropod Read Database (ASGARD) database (Zeng and Extavour, 2012) is a resource for transcriptomic data of arthropod species. Transcriptomes were assembled *de novo* from milkweed bug *Oncopeltus fasciatus*, the cricket *Gryllus bimaculatus* and amphipod crustacean *Parhyale hawaiiensis*. Putative ontology, coding region determination, protein domain identification was annotated. Assemblies can be searched by orthology annotation, gene ontology term annotation or Basic Local Alignment Search Tool. Users can download FASTA format assembly product sequences, find links to NCBI predicted orthologs data. Also, the locations of protein domains can be graphically visualized and matched to similar sequences from the NCBI. The database is useful for studies in different fields such as comparative genomics, evolutionary biology, physiology, developmental biology, phylogenomics, and ecology.

The database LeishDB of *Leishmania braziliensis* was developed by Torres *et al.* (2017) to update and improve publicly available data for non-coding RNAs (ncRNAs) and coding gene annotations of *L. braziliensis*. They used updated databases and five prediction algorithms: GENAN, GLIMMER, SNAP, RATT, and AUGUSTUS. A total of 11491 Open reading frames (ORF), including 5263 (45.80%) of them that are associated with proteins were identified. Also, they found 11,243 ncRNAs that belong to different classes distributed along the whole genome. The accuracy of their predictions was verified by the comparison of predicted sequences with those obtained from RNA-seq. The automatic predictions and annotations of non-coding sequences were performed by covariance models comparisons and sequence similarity searches.

GCGD: A Farmed Fish Database

Grass carp genome database (GCGD) was developed by Chen *et al.* (2017) to provide researchers with the centralized database of genomic data for *Ctenopharyngodon idellus*. Genome, amino-acid sequences of predicted protein-coding genes, annotations and their visualizations are included into the database. GCGD also provides an access to transcriptomic datasets, genetic linkage maps, Short Sequence Repeats. They integrated different useful tools which enable efficient data retrieval, analysis, and data visualization. For example, JBrowse provides genomic annotation navigation, BLAST enables to perform sequence alignment, EC2KEGG facilitates the comparison of metabolic pathways, IDConvert allows the conversion of terms across databases and ReadContigs facilitates the extraction of sequences from the genome of grass carp.

Plant Transcriptome Databases

Most transcriptome plant databases are dedicated to agronomically important species such as crop, tree and vegetable plants. For the crop plants, the main data repositories were created for bread wheat, rice, the burclover (*Medicago truncatula*) legume and sorghum. Vegetable and tree species such as carrot and mulberry tree (important for the mulberry-silkworm interaction), eucalyptus (commercially important for the production of paper and cellulosic ethanol) have corresponding transcriptome database resources. Other important sources include transcriptome databases of medicinal plants and metabolic pathway information.

Crop Plants

As wheat provides an estimated 20% of all the consumed calories worldwide, considerable interest in the crop drives efforts into developing more commercially advantageous varieties. Omics resources are the first port of knowledge to identify potential traits of interest which could further help to narrow down to alleles for the use in breeding programs. With this goal, the functional annotation database called dbWFA for bread wheat *Triticum aestivum* was developed in [Vincent et al. \(2013\)](#). dbWFA is based on the reference 56,954 transcripts NCBI wheat UniGene set which is an expressed gene catalogue created based on full-length 17,541 TriFLBD database coding sequences by using expressed sequence tag clustering. Annotation information from the model plant *Arabidopsis thaliana* and *Oryza sativa* L. was linked back to the *T. aestivum* sequences using BLAST-based homology searches. Putative functions were assigned to 45% of the UniGene transcripts and 81% of the TriFLDB full-length coding sequences. The database contains information on functional annotations, Gene Ontologies, gene families and metabolic pathways.

Burclover is also a forage crop of commercial interest. MtDB is a relational database ([Lamblin et al., 2003](#)) contains transcriptomic data for *Medicago truncatula* legume *M. truncatula* samples that represent various developmental stages and pathogen-challenged tissues. Unigene sets generated by different assemblers such as Phrap, Cap3 and Cap4 can be selected and compared. MtDB provides users with quick access and identification of sequences for particular research interests. To facilitate comparison between different sites, the authors performed cross-reference of sequence identifiers from all public *M. Truncatula* sites such as GenBank ID, CCGB, TIGR, NCGR, INRA. Also, the database provides hypertext links for databases for all queries' results.

Sorghum genomic data and functional annotations were collected by [Tian et al. \(2016\)](#) to create SorghumFDB database. The database provides detailed gene annotations, orthologous pairs in Arabidopsis, rice and maize, miRNA and target gene information, genome browser and gene loci conversations. It also includes the information about sorghum gene family classification such as transcription factors and regulators, carbohydrate-active enzymes, ubiquitins, protein kinases, etc. Co-expression data, protein-protein interactions, and miRNA-target pairs were used to construct a dynamic network of biological relationships.

TENOR (Transcriptome Encyclopedia Of Rice) is a database for comprehensive mRNA-seq experiments in rice that was developed by [Kawahara et al. \(2016\)](#). The database includes large-scale mRNA-seq data from rice in a wide variety of conditions. TENOR was developed to enable the scientists better understand the regulatory networks of genes responsible for adaptation to different environmental conditions. As such, the authors used mRNA-seq and applied time-course transcriptome analysis of rice (*Oryza sativa* L.), under 2 plant hormone treatment and 10 abiotic stress conditions. Differential expression analysis detected a large number of genes responsive to abiotic stress and plant hormones treatment. The online database enables users to download rice transcriptome data, co-expression data of the responsive genes, search relevant genes by keyword, genomic coordinates, and by responsive expression patterns. TENOR also includes functionality for visualization of the expression levels under various conditions for each transcript.

Tree and Vegetable Species

The CarrotDB database of *Daucus carota* L. was assembled and analyzed in [Xu et al. \(2014\)](#). They downloaded 14 carrot RNA-seq raw data from Sequence Read Archive (SRA) and National Center for Biotechnology Information (NCBI) and mapped them to the whole genome sequence. They classified a total of 2826 transcription factors (TF) into 57 families and identified them in the entire genomic sequence. Carrot-DB integrates carrot genome sequence, coding sequences, putative genes sequences, transcript sequences, etc. The part of CarrotDB called 'GERMPLASM' provides 45 carrot genotypes taproot photos and information about names, accession numbers, colors of the cortex, countries of origin, phloem and xylem.

Morus Notabilis is an important plant for sericulture and plant-insect interaction studies ([Li et al., 2014](#)). The genome and transcriptome of *M. Notabilis* were sequenced and analyzed. They developed open-access Morus Genome Database (MorusDB). The database provides access to large-scale genomic sequencing and assembly, genes and functional annotation transposable elements (TEs), gene ontology (GO) and expressed sequence tags (ESTs). To provide an access for identification of orthologous and paralogous groups of *M. Notabilis*, the most recent versions of protein sequences of related plants such as *Arabidopsis thaliana*, *Populus trichocarpa*, *Malus domestica* and *Fragaria vesca* were downloaded. Gene ontologies of *M. Notabilis* can be analyzed using Mulberry GO tool package. Gene ontologies can be searched using Search GO or obtained using gene ID and Fetch GO.

EUCANEXT ([Nascimento, 2017](#)) database is an integrated gene expression (RNAseq) and ESTs data platform with a set of the web-based tool allowing sequence similarity/keyword/transcript ID searches as well as allowing to find differentially expressed sets of genes under different custom-chosen conditions. The database is based on 14 Illumina RNA-Seq libraries and 165,268 ESTs; genome annotation information is also available with GO, orthoMCL, NR, Uniref90, Swiss-Prot, Tair and CDD terms. A genome

Table 1 Transcriptomic databases

#	Database name (short name)	Organism	Type of data	URL	Reference (PMID/DOI)

browse tool is also available as well as the statistical testing for GO terms' enrichment. Overall, the resources integrated the omics data with a user-friendly platform with a potential to incorporate more data such as microRNAs or SNPs.

Other Sources

EGENES (Masoudi-Nejad *et al.*, 2007) is an extended plant transcriptome-based database of metabolic pathway genes integrated into the KEGG (Kyoto Encyclopedia of Genes and Genomes) database. EGENES is different from the set of other transcriptome data platforms because it does not concentrate mostly on the molecular properties but covers the information on metabolism, signal transduction and the cellular cycle steps. The data comes from assembled EST contigs (base on the public ESTs) with the information on the sources as well as functional annotation and a gene/EST index available for each genome. The main distinguishing feature of EGENES is the integration of genomic and pathway information. Functional assignments are made by connecting gene sets with a list of molecules that interact with it in the cell so that a higher order biological function pathway is created. EGENES pathways are created according to the same protocols which KEGG uses for functional assignment in other species.

At the start of the database in 2006, the pathway information was compiled for 25 species with 178 manually curated unique diagrams and divided into 4 main categories: (1) metabolism (2) genetic information processing (3) environmental information processing (4) cellular processes. As of now, the current EGENES version consists of 79 plant species.

Conclusion

According to the recent of 2018 NAR Molecular Biology Database Collection report the current number of databases is 1737 (Rigden and Fernández, 2018). However, this comprehensive list covers the broad spectrum of different primary and secondary biological databases containing multiple types of "omics" data. Considering the increasing number of biological databases year by year it becomes time inefficient to find a useful resource that would fit exactly to a researcher's specific task. This review is no means comprehensive but aimed to present a current overview of the major available transcriptome sources for human, animal and plant data. This review covers 43 main transcriptomic data sources. The following Table 1 is the list of the sources discussed and provides a link to the databases as well as the publications. At a glance, most of the databases are built on human data with a particular focus on cancer and other major diseases such as Parkinson's, Alzheimer's and kidney diseases. Animal databases also reflect this focus on understanding the transcriptomic profile of major diseases with most of the transcriptome databases dedicated to model organism data crucial for understanding the processes of ageing, embryonic development (in mammals), brain transcriptome and oxygenic photosynthesis (in blue-green algae). Other animal database sources are also focused on arthropod, parasite transcriptome information with a focus on a rice pest and a leishmaniasis-causing parasite. Another database is dedicated to an important farmed fish. Plant transcriptome databases are also created and maintained with an emphasis on agriculturally-relevant species such as wheat, burdock legume, rice, sorghum and carrot. Other databases are dedicated to the economically important mulberry tree and eucalyptus as well as 79 other plant species with extended pathway information, which integrates genomic and biological function pathways. Overall, it is easy to see that technological advances and an overabundance of available data allow rapid integration with other findings and possibilities of performing advanced bioinformatics analysis and in-silico queries (e.g., gene enrichment, pathway construction, ID searches) in a user-friendly interface.

Competing Interests

The authors declared that there are no competing interests.

Fig. 1 Example workflow of basic NGS analysis on the levels of preprocessing, primary analysis and subsequent steps.

Herein, p is the probability for an incorrect base call. A second definition was introduced in 2004 by [Bennett \(2004\)](#):

$$Q_{\text{Solexa}} = -10 \log_{10} \frac{p}{1-p} \quad (2)$$

Different variants of FASTQ evolved with those two variations of quality values and are described in [Table 1](#). The Q scores in Sanger FASTQ format are encoded in printable ASCII characters 33–126, which allows assigning quality values between 0 and 93. A Q₃₀ Phred score means a base call accuracy of 99.9% and a error probability of 1 in 1.000 ($10^{-3.0}$).

The underlying FASTQ variant should be aware. There are also several tools to interconvert FASTQ formats such as Biopython (Cock *et al.*, 2009a), EMBOS (Rice *et al.*, 2000) or MAQ (Li *et al.*, 2008a).

Quality Control of Raw Data

Quality control is a crucial aspect in nearly every step of the NGS analysis pipeline. The results of sequencing data analysis are strongly dependent on the quality of raw data. Checking their quality should be the initial step of every data analysis. Errors can origin from several factors, including the library protocol, the sequencing and the wet-lab preparation. Commercial sequencing platforms provide their own quality control but erroneous reads often remain in raw data. Therefore, various metrics should be checked in the first step of a data processing pipeline. Many tools for this purpose are publicly available. One of the most common programs is **FastQC**. It allows a direct import of raw reads in different file formats and offers an initial quality control validation with multiple metrics to get a quick overview of the data. **FastQC** reports provide graphical summaries, tables and highlighted problems. But it is important to evaluate those results as they are impacted by their sequencing platforms or library types. The most important parameters to check with **FastQC** are listed below:

List Items		Basic requirements table

Basic Statistics (Total sequences, sequence length, %GC): The basic statistics section provide the total number of sequence, their length (that depend on the sequencer and the library protocol) and the GC content. The latter varies across species but there should not be a significant deviation ($>10\%$) from the expected value. All values should conform with the experiment design.

Table 1 FASTQ Variants. Quality types are explained in formula (1) and (2). The ASCII offset is needed to produce printable characters

Description	Quality type	ASCII offset	Quality range
Sanger	Phred	33	0–93
Solexa	Solexa	64	–5–62
Illumina 1.3 +	Phred	64	0–62
Illumina 1.5 +	Phred	64	3–62
Illumina 1.8 +	Phred	33	0–93

Per Base Sequence Quality: The distribution of quality scores across all bases at each read position is shown. The Phred-scaled scores are assigned by the base calling algorithms of the sequencer. Due to differences in chemistry, hardware and image processing, the Q-scores are not comparable among platforms. There is a general degradation of quality with increasing read length and it is advised to truncate bases with poor quality scores. Also mid-read drops in quality can effect the mapping efficiency.

Per Sequence Quality Scores: This reports the number of reads (y-axis) versus their mean sequence quality (x-axis). The most frequently observed mean Phred-score should be higher than 27 with an error rate below 0.2%. A significant amount of reads with an overall low quality could indicate problems during sequencing. This can commonly occur to a subset of sequences. Long-read sequencing runs tend to lower read scores. This could be rectified by quality trimming.

Per Base Sequence Content: The plot shows the proportion of each base across all read positions. Four parallel lines would be expected in a random library. Some types of libraries will induce biases in sequence composition (e.g., hexamer priming during cDNA generation produces biases at the beginning of nearly all RNA-Seq reads) (Hansen *et al.*, 2010). Furthermore bisulfite treatment converts most cytosines to thymines and results in a high difference of the relative amount of C and T.

Per Sequence GC Content: The distribution of the mean GC content of each read should follow the shape of a normal distribution. Sharper shapes indicate a contamination with a specific organism or adaptor dimers. Biologically overrepresented sequences result in small spikes. A broader shape hints at different contaminants. The peak is expected at the overall %GC of the genome. Peak shifts are caused by systematic bias.

k-mer Content: The coverage of 7-mers (subsequences of 7 nt) over each read position in the whole library should be evenly distributed. The comparison between expected and observed frequency with binomial test reports possible positionally biased enrichments of k-mers. Overrepresented sequences and random hexamer primers in RNA-Seq libraries lead to highly enriched k-mers.

Sequence	Count	Binomial p-value	Possible Source
AGGAGAGAG	1000	0.000000	AGGAGAGAG
AGGAGAGAG	1000	0.000000	AGGAGAGAG
AGGAGAGAG	1000	0.000000	AGGAGAGAG

AGGAGAGAG	1000	0.000000	AGGAGAGAG
AGGAGAGAG	1000	0.000000	AGGAGAGAG
AGGAGAGAG	1000	0.000000	AGGAGAGAG
AGGAGAGAG	1000	0.000000	AGGAGAGAG
AGGAGAGAG	1000	0.000000	AGGAGAGAG
AGGAGAGAG	1000	0.000000	AGGAGAGAG

Overrepresented Sequences: A high diversity of sequences is expected in a random fragmented library. If a sequence is represented by a significant proportion of the total library, it is considered as overrepresented. This could be caused by contamination, a low diverse library (e.g., small RNA libraries) or artifacts of adaptor sequences. These highly duplicated reads can be searched against databases of common contaminants or primer sequences and should be filtered out.

Trimming and Filtering

There are various causes for low quality bases/reads in sequencing data, as already mentioned in Section “Quality Control of Raw Data”. Some NGS applications (e.g., *de novo* assembly or detection of low frequency mutations) require high accuracy reads, because poor quality input data would result in erroneous outputs. Therefore it is desired to discard ambiguous sequence parts and keep as much as possible. A quality control of trimmed/corrected reads is recommended to exclude remaining low quality reads.

Trimming

There are two approaches to handle this problem. The first removes low quality regions from reads, which is called “trimming”. Different implementations, for instance with sliding window approaches, try to achieve the aim of keeping the longest possible high quality subsequence while cutting off poor quality bases. Trimming is advised before most NGS applications.

Available trimming tools are CUTADAPT (Martin, 2011), TRIMMOMATIC (Bolger *et al.*, 2014), PRINSEQ (Schmieder and Edwards, 2011), FASTX (Gordon, 2008) or SOLEXAQA (Cox *et al.*, 2010).

Filtering

The second method of correcting reads is superimpose them to each other. The essential assumption behind this approach is the observation, that erroneous bases occur infrequently and randomly and can be modified by the most frequent reads with this pattern. These approaches base on using multiple sequence alignments, hidden Markov models, suffix trees/arrays or k-mers, whereby the last one seems to be the most suitable (Akogwu *et al.*, 2016). Corrected reads can improve alignments or assemblies significantly. However, it is ineligible for applications with a non-uniform read distribution (e.g., RNA-Seq, see chapter 4.3) or if a low coverage is expected (e.g., ctDNA analysis or discovering of rare variants). Common filtering tools are QUAKE (Kelley *et al.*, 2010), REPTILE (Yang *et al.*, 2010), MUSKET (Liu *et al.*, 2012), SEECER (Le *et al.*, 2013) or Rcorrector (Song and Florea, 2015).

Primary Analysis

File Formats: SAM/BAM

The *de facto* standard for storing alignments is the Sequence Alignment/Map (SAM) format (Li *et al.*, 2009a). Alignment information is organized in a tabular structure in plain text. The human readable SAM format can be easily converted into Binary Alignment/Map (BAM) format, which contains the same information in a compressed, indexable, binary form. It is suitable for many alignment programs because of its flexibility. This also allows the conversion from other alignment formats. The ability of streaming records directly reduces the RAM requirements. Indexing allows a fast retrieving of alignments at a specific genomic position.

SAM & BAM (see "Relevant Websites section") files consist of an optional header section followed by the alignments. Each line of the header begins with the @ character followed by a two letter code, specified tags and their value. Supplemental information about SAM version, reference sequence, library protocol and various comments can be placed here. Each alignment line contains 11 mandatory fields, shown in Table 2.

The FLAG value of the second column can be converted in a binary number, where each bit holds the value (0 or 1) of a specific property (e.g., pairing, mapping and stranding informations). The CIGAR string (6th column) describes how the read is aligned against the reference with the possible operations (M: match; I: insert; D: deletion; N: skipped region; S: soft clipped; H: hard clipped; P: padding; =: read match; X: read mismatch) and how often they occur (As an example, the CIGAR string 34M3D specifies a sequence with 34 nucleotide bases matching to the reference and 3 deleted bases). The associated software package and library is called samtools (Li *et al.*, 2009a). It provides numerous options to:

- Convert between SAM and BAM and other formats,
- Sort alignments in BAM file according position on reference sequence,
- Index sorted BAM file for faster access,
- Extract header information or specific alignments (based on FLAG or region),
- Visualize interactively,
- Mark/remove (PCR) duplicates.

It should be mentioned here that the BAM format is also used to store raw sequence reads (called unaligned BAM), since it requires less disk space than FASTQ and the conversion between FASTQ and SAM/BAM can be performed easily. But compressing Deorowicz and Grabowski (2011) the FASTQ format also reduces its size significantly and gzipped data can be directly processed by a lot of tools.

Table 2 Description of the 11 mandatory fields of the SAM/BAM file format

Field	Name	Description
1	QNAME	Query name of read (pair)
2	FLAG	Bitwise flag (combination for various properties)
3	RNAME	Reference sequence name
4	POS	Leftmost mapping position of alignment
5	MAPQ	Mapping quality (Phred-scale)
6	CIGAR	CIGAR string (notation for variants)
7	RNEXT	Reference name of mate
8	PNEXT	Position of mate
9	TLEN	Template length (insert size)
10	SEQ	Query sequence
11	QUAL	Query quality (Phred score)

Note: Modified from Li H., *et al.*, 2009. The sequence alignment/map format and SAMtools. Bioinformatics 25 (16), 2078–2079.

Sequence Alignment

Sequence alignment describes the arrangement of two or more DNA/RNA/protein sequences based on their similarity. In the field of NGS, this method is used to align short reads to a reference sequence, also called read mapping. Alignments are crucial for whole genome sequencing, exome sequencing, transcriptome sequencing, ChIP-Seq and much more applications. Reference sequences can be obtained from public databases and are usually stored in FASTA format. Current next-generation sequencers produce hundreds of million reads with a typically length > 200 bp per run and represent them in FASTQ files.

Sequence alignment is not as CPU-intensive as assembly but yet not trivial. Depending on the size of the input files (sequencers with one terabases throughput are available), powerful hardware is still required. Due the short lengths of reads, there may be multiple matching positions on the reference sequence. Genomes of many organisms contain highly repetitive elements (half of the human genome belongs to known families of transposable elements Schmid and Deininger, 1975, Treangen and Salzberg, 2013), therefore it is commonly encountered that reads can not span the repeats and they map at multiple positions. The resequenced DNA always differs from the reference sequence. Small structural variations such as InDels (insertions or deletions of a single base) and substitutions must be considered. Ambiguous reads can not be aligned with confidence if there occur several multiple alignments with the same similarity scores. Furthermore, these problems are exacerbated by sequencing errors of reads and reference sequence.

To process the ever increasing number of reads in an acceptable amount of time, traditional dynamic programming algorithms, Needleman Wunsch alike, are not applicable anymore. Efficiency can be gained by preprocessing the reads, the reference sequence, or sometimes both. Two methods stand out here: hashing and Burrows-Wheeler transformation. All algorithms relying on hash tables follow the seed-and-extend strategy, which was already used by BLAST (Altschul *et al.*, 1990). Notable aligners basing on this methods are MAQ (Li *et al.*, 2008a; Homer *et al.*, 2009) and SSAHA2 (Ning *et al.*, 2001).

Another clever approach is using data structures such as prefix/suffix trees/arrays. Several tools employ those with Burrows-Wheeler transform (BWT), an algorithm origins from text data compression. The authors of BWA (Li and Durbin, 2009) explain this method in detail in their paper. Further aligners using this strategy are BOWTIE2 (Langmead *et al.*, 2009), and SOAP (Li *et al.*, 2008b). HISAT2 (Kim *et al.*, 2015), TOPHAT2 (Kim *et al.*, 2013) and STAR (Dobin *et al.*, 2013) provide extended functionality, such as spliced alignments and should be considered for mapping RNA-Seq data.

Both methods have their strengths and weaknesses to be aware of. Hashing methods show good results with erroneous reads. A drawback is the increased runtime with seeds on highly repeated sequences, because the extend step is performed for every seed. This is the advantage of BWT aligners, as all matching positions are joined in one path. On the downside, they have difficulties to resolve sequencing errors.

Last but not least, the correct implementation is important regarding feasibility and runtime. Hard disk I/O operation are extremely slow. Keeping required data in CPU cache or RAM speeds up analysis. Furthermore, mapping is highly parallelizable and many aligners provide the option to use multiple cores/threads. To increase sensitivity and specificity of the alignment, paired end (PE) and mate-pair (MP) mapping should be regarded. Although the size of FASTA is significantly smaller than that of FASTQ, the additional quality values improve alignment accuracy remarkably.

Alignment quality control is essential, even if used reads passed their raw QC. Distinct NGS applications have different control parameters to be regarded. Overall mapping rate is a general metric to be observed. In case of exome sequencing the proportion of reads mapped to targeted exon regions is of importance to estimate the capture efficiency. The mean/median read coverage and percentage of the covered genome are relevant, especially for whole genome sequencing. Moreover, SAM/BAM files provide the mapping quality and insert size for each read.

Programs to be considered for QC are BAMSTATS (Ashelford, 2011), PICARD TOOLS (Picard-Team, 2017), QPLOT (Li *et al.*, 2013) and the Genome Analysis Tool Kit (GATK) (McKenna *et al.*, 2010).

Genome/Transcriptome Assembly

Assembling in bioinformatics describes the reconstruction of a longer sequence from smaller fragments. This is a computational challenging task, especially for large and complex genomes (e.g., from humans and plants), because each read has to be compared with every other read. Repetitive DNA sequences, heterozygosity, high ploidy, and transposons makes it arduous to assemble the genome from short (paired end) reads. Using very long reads (e.g., PacBio Systems) and mate pair libraries with various insert sizes will facilitate and improve the assembly. The general procedure is assembling NGS reads into larger contiguous sequences, called contigs. This is the first step of assembling followed by the arranging of contigs in scaffolds in their right order, orientation and distance. Gaps (caused by repeats or no coverage) between contigs are filled by N's instead of nucleotides. Next, all scaffolds that belong to the same chromosome are arranged in one sequence. Closing all gaps completes the assembly.

It is hard, labor-intensive and expensive to achieve a complete assembly at the chromosome-level. Many genome assemblies are already available in public databases. It is recommended to always align to accessible reference genomes, because it improves and accelerates the assembly. Reconstructing genome or transcriptome sequences without using a reference is called *de novo* assembly. Numerous software tools are available, but they vary strongly with respect to their performance, hardware requirements and output. Therefore no general recommendation is possible. Various teams compete periodically in the Assemblathon (see "Relevant Websites section") to compare different assemblers and methods. Assemblathon 1 (Earl *et al.*, 2011) and 2 (Bradnam *et al.*, 2013) revealed that one assembler may perform well in one situation (e.g., one species) but will not work as well in other situations. Two methods are utilized by most assemblers and will be described in the next sections.

Overlap-layout-consensus method

As the name implies, Overlap-Layout-Consensus (OLC) works in three stages:

- O pairwise alignments of all reads find overlaps and construct a graph of reads (nodes) and overlaps (edges),
- L overlapping reads are ordered to identify redundant reads which are removed during the layout step,
- C finally, the most likely nucleotides are chosen to build a consensus sequence.

CELERA (Myers, 2000), ARACHNE (Batoglou *et al.*, 2002), SGA (Simpson *et al.*, 2012) and NEWBLER (Margulies *et al.*, 2006) are exemplary mentioned assemblers using the OLC method.

de Bruijn graph method

The de Bruijn Graph (DBG) approach chops all reads into short strings of a fixed size k . A directed graph is built by connecting k -mers, where adjacent nodes overlap by $k-1$ nucleotides. The number of matches from short reads to each node is tracked. The genome sequence can be constructed following the paths in the graph and those node coverages. The layout step is a Hamiltonian path problem (NP hard) and building the consensus sequence requires multiple sequence alignments, which is very CPU consuming. Constructing the contig sequence in DBG approach infers the Euler path problem and does not require read alignments, which is algorithmically easier to solve and more CPU/RAM efficiently. DBG approaches seem to perform better with large NGS datasets.

Common DBG-tools are SOAPDENOV2 (Luo *et al.*, 2012) ALLPATHS-LG (Gnerre *et al.*, 2011), ABYSS (Simpson *et al.*, 2009) and VELVET (Zerbino and Birney, 2008).

Transcriptome reconstruction

Assemblers, as e.g., TRINITY (Grabherr *et al.*, 2013), SOAPDENOV-TRANS (Xie *et al.*, 2014), OASES (Schulz *et al.*, 2012) and TRANS-ABYSS (Robertson *et al.*, 2010) are mentioned here for the transcriptome reconstruction using RNA-Seq data instead of DNA. The challenge of RNA-based assembly is the high coverage caused by gene expression. These tools are also capable to detect splicing events and can reconstruct different isoforms. It is suggested to combine several assemblers and methods for better results.

The assembly quality can be evaluated by different metrics, such as N50, multiplicity or coverage. Especially the contig or scaffold lengths are used to describe the completeness of draft assemblies. The N50 statistic characterizes the length distribution of contigs and can be seen as a weighted median. In an set of contigs, ordered by their lengths, N50 is the length of the contig at 50% of total assembly length. That means at least 50% of the nucleotides of the entire assembly are contained in contigs with the N50 length or longer. Linked to this value is the L50 metric, which represents the number of contigs whose lengths form the N50.

The authors of the Assemblathon (Bradnam *et al.*, 2013) proposed ten different metrics, which should be weighted to the own demands.

Secondary Analysis

Formats: VCF

The Variant Call Format (VCF) (Danecek *et al.*, 2011) is a text file format for storing DNA variations, such as single nucleotide variant (SNV), InDels and structural variations (SVs) together with annotations. It was developed for the 1000 Genomes Project with the aim of representing a wide variety of genomic variations regarding one reference. Therefore it stores only variations and no redundant genetic data are stored e.g., in the General Feature Format (GFF). Compressing saves disk space and indexing allows fast data access. A collection of tools to filter, compare, summarize and convert VCF files is combined in the VCFtools package.

A VCF file is segmented in a header and a data section. Lines starting with `##` define the header and provide space for meta information. Special keywords allow an easy parsing. The line starting with a single `#` character marks the field definition and beginning of the data section. Each data line corresponds to a variant at one genomic position or region. They are tab separated in 8 mandatory fields, which are described in Table 3.

Table 3 Description of the fields of the VCF format

Field	Name	Description
1	Chrom	name of reference sequence (typically chromosome)
2	POS	position of variation on reference
3	ID	unique identifier, e.g., dbSNP ID
4	REF	Reference allele
5	ALT	comma-separated list of alternate alleles
6	QUAL	associated quality score (Phred-scale)
7	FILTER	FLAG for site filtering information
8	INFO	user extensible annotation
9	FORMAT	(optional) genotype fields
10	SAMPLE	(optional) sample identifiers

Variant Discovery

Single nucleotide variants

Variant discovery is an important procedure for a lot of whole genome sequencing (WGS) and whole exome sequencing (WES) experiments due the fact of differences between the reference and the sequenced individual. The most abundant genomic variation is the substitution of a single nucleotide base, called single nucleotide variant (SNV). Synonymous SNVs are called single nucleotide polymorphism (SNP). SNVs are often used as genetic markers in genome-wide association studies (GWAS), especially if they are related to diseases.

Another form of genomic variations are insertions or deletions of a single base, also called InDels (Note that in this context an InDel is only *a* single base variation and that an insertion/deletion of multiple bases is considered multiple consecutive InDels). There is a variety of algorithms for SNV detection based on probabilistic or heuristic methods. One has to distinguish SNVs from sequencing errors or other systematic biases. Another common source of error are misalignments. GATK offers a local realignment function around SNVs and InDels to minimize errors due misalignments.

Common tools for SNP calling are FREEBAYES (Garrison and Marth, 2012), SAMTOOLS MPILEUP, SOAPsnp (Li *et al.*, 2009b), VARSCAN (Koboldt *et al.*, 2009) and GATKs HAPLOTYPECALLER.

Structural variations

Structural variations (SV) affect larger sequence fragments (> 50 nucleotides (Mills *et al.*, 2011)). They include insertions, deletions, duplications, translocations and inversions. SVs can be assessed by four approaches, which are shortly described below:

Assembly In general the assembly method is capable to detect all possible SV. However, assembling is error-prone, as described in chapter 3.3. It is recommended to use a reference-assisted local assembly instead a *de novo* whole genome assembly. It is also advised to reduce the set of reads to ones, that are missing a mate or had other mapping difficulties in this region.

Read pair (RP) SVs are detected by odd mapping patterns. Differences between expected library insert size and distances of mapped read pairs point as insertions, if the mapping distance shorter than the insert size or as deletions (vice versa). Translocations and inversions can cause different relative mapping orientation of a read pair.

Split read (SR) Split read analysis show similarities to the RP method but the breakpoint of the variant is located directly at the reads. It is necessary to split the read in two or more fragments and realign them independently. Breakpoints can be detected on single base level, however short fragments may map at many genomic positions. After aligning the fragments successful, SVs can be determined by distance and orientation.

Read depth (RD) The read coverage of unique genomic regions should be equally distributed. Deletions and duplications result in significantly lower or higher read depth and copy number variants of large regions can be discovered easily. Insertions of (novel) sequences or inversions are not detectable through this method.

Numerous tools utilize a combination of these methods to reach a higher specificity and sensitivity for SV detection. BREAKDANCER (Chen *et al.*, 2009), CNVNATOR (Abyzov *et al.*, 2011), DELLY (Rausch *et al.*, 2012), HYDRA (Quinlan *et al.*, 2010) and PINDEL (Ye *et al.*, 2009) are mentioned here as examples.

Expression Analysis

Sequencing mRNA, an intermediate between genome and proteome has a broad variety of applications in life sciences. RNA-seq enables a combined identification and quantification of gene activity and associated mechanisms. The diversity of scientific questions of interests makes it impossible to provide an universal analysis approach. One primary objective is gene expression profiling between samples.

A typical workflow begins with the mapping of quality controlled RNA-Seq reads to a reference genome/transcriptome or *de novo* assembled contigs. This step is followed up by an identification of transcripts, exons or genes. Tools, such as CUFFLINKS (Trapnell *et al.*, 2010) and STRINGTIE (Pertea *et al.*, 2015), assemble transcripts of each data set and estimate their expression levels. Using a spliced alignment as input (e.g., from TOPHAT2 or HISAT2) allows to summarize novel transcripts and spliced isoforms along with annotated genes.

Normalization

First, all transcript assemblies from different RNA-seq libraries must be merged to one master transcriptome. The next essential step is the normalization of expression values to enable comparisons within and between samples. Intralibrary normalization allows the quantification of genes with different lengths. A common method is calculating RPKM/FPKM (reads/fragments per kilobase exon per million mapped reads) values. Comparing expression levels of individual genes between samples requires interlibrary normalization. A simple approach is the adjustment with respect to the library size but there are further methods, such as different scaling factors or quantile normalization. Multiple methods are described and compared by Risso *et al.* (2014), Li *et al.* (2015), Bullard *et al.* (2010).

Differential expression

Differential expression analysis aims to detect genes, which significantly differ in their expression level across samples/conditions. RNA-Seq offers a wide dynamic range and a low background noise but inherits other difficulties, such as non-uniform read coverage distribution and sequencing biases through nucleotide compositions. Different statistical models and methods to counter these are implemented in several tools and packages. Many of them are part of Bioconductor (Huber *et al.*, 2015) and based on the statistical programming language R (R Core Team, 2017).

DESeq2 (Love *et al.*, 2014), edgeR (Robinson *et al.*, 2010), LIMMA (Ritchie *et al.*, 2015), EBSeg (Leng and Kendziorski, 2015), BALLGOWN (Frazee *et al.*, 2015) and BAYSeq (Hardcastle, 2012) are notable representatives. The Basic Tuxedo Suite (Trapnell *et al.*, 2012) (including BOWTIE TOPHAT CUFFLINKS CUMMERBUND (Goff *et al.*, 2013)) and the “new Tuxedo” protocol (Pertea *et al.*, 2016) (HISAT, STRINGTIE, BALLGOWN) offer a complete RNA-Seq pipeline. There are also fast methods to estimate abundances without aligning reads. SALMON (Patro *et al.*, 2015), SAILFISH (Patro *et al.*, 2014), KALLISTO (Bray *et al.*, 2015) and RSEM (Li and Dewey, 2011) should be noted. However, it is important to choose tools and workflow fitting to the experiment settings. All tools offer detailed documentations and examples, which should be regarded.

Genome Annotation

Even perfect assembled genome sequences are mostly useless if they are not complemented by biological relevant information. This information includes location, structure and function of genes and gene models. The process of assigning biological

information to pure sequence data is called annotation. A high quality annotation is expensive and labor-intensive, so most genome projects rely on automated gene annotation, but still requires editing by human experts. The basic steps are described below.

First annotation step

First of all, it should be noted that annotation strongly depends on the quality of the genome assembly. The automated annotation process can roughly be divided in two phases: A computational prediction phase and a synthesizing annotation phase.

Repeat identification is the first step to mask repetitive sequences, low complexity regions and transposable elements. Excluding those repeats with tools like REPEATMASKER (Smit *et al.*, 2013) prevents numerous false annotations.

The next step is the *AB INITIO* gene prediction to identify genes using mathematical models. This is done by scanning for open reading frames (ORF) and training for species-specific traits like codon frequencies. Programs like AUGUSTUS (Stanke *et al.*, 2006) or GENEMARK (Lomsadze *et al.*, 2014) implemented this approach but are usually limited to find coding sequences (CDS). Improvements can be gained by aligning external evidence, such as transcript or protein sequences from related organisms.

Mapping ESTs and RNA-Seq data extends evidence for UTRs and provides additional splice sites. GNOMON (Souvorov *et al.*, 2010) and the PASA (Haas *et al.*, 2011) pipeline support this feature. Protein sequences from related organisms can be obtained from UniProt/SwissProt (Wasmuth and Lima, 2016) and are aligned by BLAST (Altschul *et al.*, 1990).

Second annotation step

The second annotation phase synthesizes the results of the *ab initio* prediction into a consensus set of gene annotations. Evidence from external sources are weighted and the most representative gene model is chosen. This is incorporated in automated pipelines, such as MAKER (Cantarel *et al.*, 2008), PASA and GLEAN (Elsik *et al.*, 2007). However, manual curation is advised to detect systematic problems.

Conclusion

The field of NGS technologies is constantly evolving and novel methods become a routine part in biological and medical applications. e.g., ultra deep sequencing or read lengths of several hundred kb were considered as impossible a few years ago. There are also approaches which seem to be very promising today. Beside their advantages, challenges which cannot be solved satisfactorily, may cause a future disappearance of this technology. Nevertheless, every advancement or shift in technology requires adjustments of analyzing software. Hardware- and time requirements must be considered, too. Best results can be achieved by combining different methods and tools which fulfill the desired demands.

Introduction

Cells are built, developed, and reproduced by genetic instructions stored in the form of DNA, a long double-stranded molecule of nucleic acids. DNA is *transcribed* into RNA, which is then *translated* into proteins to carry out the duties specified by the instructions encoded in the genes. The complete set of RNA transcripts produced by the genome, under a specific condition or in a specific cell, is called transcriptome (Adams, 2008). Transcriptomics is the study of the transcriptome through which researchers gain insight into gene activities and better understand how cells normally function or how changes in RNA activities can contribute to disease (Kalia and Gupta, 2005). Transcriptomes can basically enable researchers to depict a comprehensive, genome-wide picture of gene activities across different cells (Adams, 2008). In addition, comparative transcriptomics facilitates the study of the evolution of gene regulation and provides deeper understanding of the species conservation at the molecular level (Breschi *et al.*, 2017).

Transcriptomics has been characterized by technological innovations that continuously transform the field. Key contemporary transcriptomic technologies include DNA microarrays and NGS technologies called RNA-seq. Microarrays measure the expressions of a predetermined set of sequences while RNA-seq uses high-throughput sequencing to capture all sequences (Lowe *et al.*, 2017a). Transcription can also be studied at the level of individual cells using single-cell transcriptomic techniques, for example, single-cell RNA-seq (Kanter and Kalisky, 2015).

Analysis of microarray or RNA-seq data relies on the hypothesis that the measured values (e.g., florescent intensities or read counts) for each RNA represent its relative expression level in a specific sample under study. To compare RNAs across multiple samples and to reveal biologically relevant patterns of gene expression, transcriptomic data shall undergo a preprocessing transformation step referred to as normalization. Normalization adjusts for technical biases and other systematic variations to balance intensities or read counts appropriately so that meaningful biological comparisons can be made (Quackenbush, 2002; Mortazavi *et al.*, 2008). Although microarray and RNA-seq experiments carry different sources of systematic variations, it has been shown that normalization is an essential step in the analysis of expression data derived from both technologies (e.g., Park *et al.*, 2003a; Bullard *et al.*, 2010).

Several normalization methods developed during the past decades. They mainly focus on the mean and the variance, which are quantifying the center and the spread of the data, respectively. These methods try to adjust mean and variance between different samples. Fig. 1, for instance, shows how normalization would adjust the distribution of RNA expressions across different samples.

Microarray Data Normalization

A microarray is a laboratory tool used to quantify the expression of tens of thousands of genes simultaneously. DNA microarrays (a.k.a. biochips or DNA chips) are glass, plastic, or silicon-based slides printed with thousands of microscopic spots in defined positions, with each spot containing picomoles (10^{-12} mol) of a specific DNA sequence. The DNA molecules attached to a microarray slide act as probes to capture messenger RNA (mRNA) transcripts expressed by genes.

A microarray experiment typically starts with purification of mRNAs from the biological sample (i.e., RNA isolation). RNAs are converted into complementary DNA (cDNA) using reverse transcriptase enzyme and labeled with fluorescent dyes (e.g., cyanine dyes, a synthetic dye family belonging to polymethine group). After labeling, cDNA molecules are allowed to bind or *hybridize* to the DNA probes on the microarray slide. The microarray is then scanned to visualize fluorescence intensities that measure the expression of each gene printed on the slide – that is, brighter spots indicates higher level of expressions.

DNA microarrays come in *two-channel* versus *one-channel* designs. Two-channel or two-color microarrays are hybridized with cDNA prepared from two samples to be compared (e.g., diseased versus healthy tissues) and labeled with two different fluorophores (i.e., Cy3 and Cy5 for green and red fluorescence emission, respectively). Relative intensities of each fluorophore through a ratio-based analysis can then identify downregulated and upregulated genes. A single-channel or one-color microarray is hybridized with one sample and the array provides intensity data for each probe as the relative level of hybridization with the labeled cDNA or the expression level of the corresponding gene. Fig. 2 illustrates key steps of a typical DNA microarray experiment and analysis of resulting expression values.

Several technical errors may occur during the microarray experimental procedure such as irregular spot printing, nonuniform intensity of the fluorescent compound, dusty arrays, purification errors, difference in efficiency of labeling via fluorescent dyes, hybridization efficiencies, and systematic biases in quantified expression levels (Quackenbush, 2002; Park *et al.*, 2003b; Yang *et al.*, 2002). These artifacts have bearings on capturing data leading to different measurements of same expression values. Hence, this is important to eliminate technical noises prior to any downstream analysis and normalization plays an important role in reducing potential systematic noises.

Fig. 1 Sample boxplots. Box plots of $\log_2(\text{expression})$ array data before and after normalization. Dataset: GSE4158, normalization method: Quantile normalization implemented using “Rnits” R package (Sangurdekar, 2014).

Key steps of microarray experiment & analysis pipeline

Fig. 2 Microarray workflow. Key steps of performing a microarray experiment for gene expression studies after sample preparation. Raw expression data will be preprocessed to assure the data quality and then undergo various downstream analyses.

There are several normalization methods. Some have been developed for particular platforms and the analysis may be proprietary for commercial platforms. Yet, several freely accessible resources are available to normalize microarray data including various Bioconductor R packages (see “Relevant Websites section”). Selecting the best normalization method is not an obvious decision and suitable choices may vary depending on the data under study. Complex methods do not guarantee better performance and background assumptions may add bias and eliminate important data (Park *et al.*, 2003a). Nonetheless, there are several scientific works comparing the performance of different normalization methods with respect to different performance criteria (Smyth and Speed, 2003; Bolstad *et al.*, 2003; Park *et al.*, 2003b) which can help to opt for an appropriate normalization method based on the experimental platform and the quality of the data under study.

MA plot (Dudoit *et al.*, 2002) is a visualization tool traditionally used to assess the performance of normalization methods by revealing systematic intensity-dependent effects in the measurements taken from two samples. We denote two, that is, query and

Fig. 3 Sample MA plots. MA plots before and after normalization using smoothScatter method which produces a smoothed color density representation of a scatterplot. Red line is the lowest smoothed line to visually show the bias. Dataset: Dilution (array 20B v 10A) from “affydata” R package. Reproduced from Gautier, L. 2011. Affydata: Affymetrix Data for Demonstration Purpose. R package version, 1, 18. Normalization method: Quantile normalization implemented using “affy” R package. Reproduced from Gautier, L., Cope, L., Bolstad, B.M., Irizarry, R.A., 2004. Affy – Analysis of Affymetrix GeneChip data at the probe level. *Bioinformatics* 20, 307–315.

reference, samples as R and G (for the red and green colors commonly used to represent Cy5 and Cy3 intensities in two-channel microarrays). MA plot is a scatter plot whose y -axis and x -axis respectively display $M = \log_2(R_i/G_i)$ and $A = \log_2(R_i * G_i)$ where R_i and G_i represent the intensity of the i th gene in R and G samples. An underlying assumption in many microarray gene expression experiments is that most of the genes do not change in their expressions, and thus the majority of the points would have 0 y -coordinate and lie on the x -axis, that is, $M = \log_2(1) = 0$. If this is not the case, a proper normalization method should be applied to the data to adjust imbalanced intensities. **Fig. 3** shows MA plots for a sample before and after normalization.

Lowess Normalization

Lowess/loess normalization is one of the earliest developments in microarray normalization proposed by Terry Speed’s group (Dudoit *et al.*, 2002; Yang *et al.*, 2002). They observed nonlinear bias in two-color log ratios changing as a function of average intensities in two-channel microarrays (as seen in MA plots). Similar bias has been also observed in single-channel arrays when plotting intensities in one chip against intensities averaged over all chips (Reimers, 2010).

The purpose of lowess normalization is to estimate this bias using a nonparametric curve known as *local weighted regression* (lowess). At each point on MA plot, M value is adjusted by subtracting the estimated bias (the height of the loess curve) at the same A value, that is, $\log_2(R/G) = \log_2(R/G) - c(A)$, where $c(A)$ is the lowess fit to MA plot. Lowess normalization operates on individual chips (within-chip normalization), but was intended to make measures comparable across chips as well (between-chip normalization). It can perform robust locally linear fits not affected by outliers in the MA plot (Yang *et al.*, 2002).

Lowess normalization was further improved by Speed’s group to account for spatial dependence in dye biases (Yang *et al.*, 2002) which was based on the observation that there were pronounced differences in the lowess curves fit to log ratios in different regions of the same chip. Accordingly, they proposed *within print-tip group normalization*, which aims at fitting separate lowess curves to each “print tip,” that is, $\log_2(R/G) = \log_2(R/G) - c_i(A)$, where $c_i(A)$ is the lowess fit to MA plot for the i th print tip only. A print tip is a set of probes on a common grid of a robotically printed cDNA array.

Researchers continued to further complicate lowess normalization adjusting for other possible biases. Examples include rescaling variation within each print-tip group or estimating a plate order effect (see, e.g., Smyth, 2002; Smyth and Speed, 2003).

Quantile Normalization

Quantile normalization is a simple nonparametric normalization method initially proposed for single-channel arrays (Bolstad *et al.*, 2003). It is a between-array normalization method that makes the distribution of all arrays identical in statistical properties. The algorithm maps every expression value on each chip to the corresponding quantile of a reference distribution that is determined by pooling across distributions of all individual chips. It is motivated by the idea that a quantile–quantile plot shows that the distribution of two data vectors is the same only if the plot is a straight diagonal line.

While being simple and fast, quantile normalization could outperform most of the more complex contemporary methods including loess. It has been widely used for normalization of single-channel high intensity oligonucleotide arrays, such as

Affymetrix arrays (one of the most frequently used platforms for microarray experiments), and is also applicable to dual-channel chips (Reimers, 2010). Quantile normalization was made available as the default normalization method in the widely used “affy” package of R Bioconductor, which contains functions for exploratory oligonucleotide array analysis (Gautier *et al.*, 2004).

Despite its clear advantages, quantile normalization explicitly assumes that the distribution of gene expression measures is identical across the samples. This can be violated when there are biologically meaningful differences between samples’ transcriptomic distributions (e.g., when studying treatments with severe effects on the transcriptome, or cancer samples with severe genomic aberrations). Also, in its canonical form, quantile normalization forces genes with high intensities into the reference distribution shape which may reduce biological differences (Reimers, 2010). The latter has been addressed in a later version of the “affy” package.

Overall, due to its simplicity, efficiency, generality, and availability, quantile normalization has become a comparatively popular choice of normalization for microarray data.

Variance Stabilization

Various widely used standard statistical methods (e.g., regression, ANOVA) assume that data is normally or symmetrically distributed with a constant variance not depending on the mean of the data. However, microarray data fail to comply with this canonical assumption underlying standard methodologies (Rocke and Durbin, 2001). It is therefore a common practice to stabilize the variance of microarray expression values by transforming the expression values to a logarithmic base 2 scale. While logarithmic transformation makes variations among measurements that span several orders of magnitudes comparable, it can inflate variances of low-level, near-background observations (Durbin *et al.*, 2002), which may necessitate removal of low-intensity probes a priori. To address this issue, (Durbin *et al.*, 2002) introduced a transformation that stabilizes the variance of microarray data across the full range of expression values without needing to remove low-level observations. For more details and other options, interested readers may wish to consult (Durbin *et al.*, 2002; Huber *et al.*, 2002; Durbin and Rocke, 2004; Lin *et al.*, 2008).

Nonetheless, while more sophisticated methods may provide more coherent variance stabilization, the ultimate gain is possibly small compared to the simplicity of log transformation (Speed, 2001) and thus, researchers usually stick by log2 transformation.

RNA-seq Data Normalization

RNA-seq uses next-generation sequencing (NGS) to quantify the presence and abundance of RNAs in a biological sample at a specific moment of time. It is a revolutionary tool that provides a comprehensive view of the transcriptome, and enables the detection of novel transcripts and characterization of alternative splicing (Wang *et al.*, 2009). It is rapidly replacing gene expression microarrays for whole-genome transcriptome profiling (Mortazavi *et al.*, 2008; Nagalakshmi *et al.*, 2010). That is basically due to limitations involved in microarray-based experiments that have been resolved using RNA-seq technologies. For example, RNA-seq intrinsically avoids errors introduced during hybridization of microarrays as it does not depend on genome annotation for prior probe selection. RNA-seq also captures a broader dynamic range that ensures the detection of more differentially expressed genes with higher fold-change compared to microarrays (Zhao *et al.*, 2014).

A typical RNA-seq experiment consists of RNA purification and isolation, library preparation (i.e., converting RNA to cDNA and adding sequencing adapters), sequencing using a NGS platform, and analysis of resulting sequencing reads (Fig. 4(a)). RNA-seq analysis pipeline usually involves demultiplexing and trimming sequencing reads, mapping sequencing reads to a reference transcriptome, annotating transcripts to which reads are mapped, counting mapped reads to estimate the abundance of transcripts, normalizing reads, and performing downstream statistical analyses – for example, identifying differentially expressed genes, visualization, etc. (Fig. 4(b)).

Although RNA-seq experiments do not suffer from technical noises inherent to microarray technologies, they are still subject to some systematic variations such as library size (i.e., sequencing depth) differences between samples, as well as transcript length bias and GC content within a specific sample (Oshlack and Wakefield, 2009b). It is therefore essential to normalize data in order to adjust for such biases. Several normalization methods have been developed for RNA-seq data. Some of the most frequently used ones have been reviewed in here.

Total Count

Differences in the library size (i.e., sequencing depth) account for the most apparent source of intersample variations in RNA-seq experimentations. Therefore, the simplest form of between-sample normalization has been realized by scaling raw read counts in each sample (or sequencing “lane”) by a sample-specific factor (Dillies *et al.*, 2013).

In total count (TC) normalization, for each sample, gene counts are divided by the sample’s library size (i.e., total number of mapped reads associated with that sample) and multiplied by the mean TC across all the samples of the dataset.

Upper Quartile

Upper quartile (UQ) normalization is very similar to TC and only replaces the TCs (i.e., library size) by the UQ (75th percentile) of read counts, after excluding genes with zero reads across all lanes (Bullard *et al.*, 2010).

Reads Per Kilo Base Per Million Mapped Reads

This approach was aimed to facilitate comparison of transcript levels both within and between samples as it rescales gene counts to correct for differences in both library sizes and gene length (Mortazavi *et al.*, 2008). Two replicate samples with different total library size would have proportionally different sequenced reads mapped to the same gene. Also, longer transcripts can potentially produce more fragments than shorter ones. To adjust for these variations, reads per kilo base per million mapped reads (RPKM) divides gene counts by the library size as well as the length of the transcript in kilobase. It has been shown that adjusting differences in gene length can potentially introduce bias in per-gene variances, in particular for lowly expressed genes (Oshlack and Wakefield, 2009a). Nonetheless, RPKM is a widely held choice in many practical applications. ERANGE tool (website available at “Relevant Websites section”) implements RPKM normalization method (Mortazavi *et al.*, 2008).

Trimmed Mean of M-Values

This normalization method assumes that most genes are not differentially expressed. Trimmed Mean of M-values (TMM) considers one sample as a reference sample and the others as test samples. For each test sample, it then computes the TMM normalization factor as the weighted mean of log ratios (i.e., *M* values) between this test and the reference, after trimming genes based on a predefined percentage of *M* values and absolute intensities. This TMM factor should be close to 1 according to the underlying assumption (i.e., low proportion of differentially expressed genes). Otherwise, the library sizes shall be corrected by TMM normalization factor to satisfy the assumption. These normalization factors are rescaled by the mean of the normalized library sizes. Raw read counts are then divided by rescaled normalization factors to obtain normalized read counts. TMM normalization has been implemented in ‘edgeR’ Bioconductor R package, version 2.5 (Robinson *et al.*, 2010).

DESeq

Similar to TMM, DESeq normalization method assumes that most genes are not differentially expressed – that is, have the same read counts across all samples (Anders and Huber, 2010). For each gene in a given sample, a DESeq scaling factor is computed as the median of the ratio of the gene’s read count over its geometric mean across all samples. The underlying hypothesis (i.e., low number of differentially expressed genes) assumes that this ratio is close to 1. Accordingly, the median of this ratio for the sample provides an estimate of the normalization factor to be applied to all read counts of this sample to fulfill the assumption. DESeq normalization is included in Bioconductor R package DESeq, version 1.30.0 (Anders and Huber, 2010). DESeq normalization factor adjusts for differences in sequencing depth between samples. An improved version of this method, implemented in DESeq2

Bioconductor package version 1.18.1 (Love *et al.*, 2014), calculates *gene-specific* normalization factors to account for further sources of technical biases such as differing dependence on GC content, gene length, etc. Interested readers can consult (Love *et al.*, 2014) for more details.

Single-Cell RNA-seq

Single-cell RNA sequencing (scRNA-seq) is becoming a powerful tool for high-throughput, high-resolution transcriptomic analysis of individual cells yielding new insights into the cellular diversity underlying homogeneous populations (Tang *et al.*, 2009). It has enabled scientists to investigate fundamental research questions not previously addressable by bulk-level experiments – for example, identifying novel cell types, unraveling tumor heterogeneity, and finding novel microbiome identities (Shapiro *et al.*, 2013).

Currently, scRNA-seq experimental pipeline typically includes isolation of single cell and RNA, reverse transcription (i.e., creation of cDNA from RNA templates), amplification, library generation, sequencing, data preprocessing and downstream analyses. Normalization is a critical data preprocessing step to adjust for unwanted biological effects and technical biases specific to the technology of interest. A distinctive feature of RNA-seq data is “zero inflation,” that is, the high proportion of zero read counts (Pierson and Yau, 2015). Single-cell RNA-seq data are also highly heterogeneous as individual cells are captured from potentially very different cell types (Finak *et al.*, 2015).

Nonetheless, the majority of currently available scRNA-seq analysis tools rely on normalization methods developed for bulk RNA-seq (Vallejos *et al.*, 2017). Given that the assumptions underlying most bulk RNA-seq normalization techniques do not necessarily apply to the single-cell setting, using existing normalization methods for scRNA-seq data may introduce artifacts that bias downstream analyses (Bacher *et al.*, 2017).

Recent methods have been proposed for scRNA-seq normalization specifically. Some of these methods rely on RNA *spike-in* controls (i.e., RNA transcripts of known sequence and quantity used to calibrate expression measurements) such as GRM (Ding *et al.*, 2015) and SAMstrt (Katayama *et al.*, 2013). However, it has been recently observed that the performance of spike-ins in scRNA-seq is often compromised, and have not been used for normalization in many laboratories (Bacher *et al.*, 2017). Here, we therefore only elaborate on two recently developed, state-of-the-art scRNA-seq normalization methods that do not require spike-ins – that is, Scnorm (Bacher *et al.*, 2017) and Scrn (Lun *et al.*, 2016). Nevertheless, bulk-based approaches as well as methods particularly tailored to scRNA-seq data have been compared in a recent review (Vallejos *et al.*, 2017) to which interested readers are referred for further details.

Scran

This method estimates cell-specific size factors from pools of cells to enhance normalization accuracy in the presence of zero inflation and unbalanced differential expression of genes across groups of cells. Scran normalization consists of the following key steps (Lun *et al.*, 2016):

- (1) Defining pools of cells: to alleviate the problem of data heterogeneity, scran preclusters cells into smaller, more homogeneous sets and perform normalization for each cluster before between-cluster normalization.
- (2) Summing expression values across all cells in each pool: summation across cells results in fewer zeroes in each pool, which implies that the subsequent normalization is less susceptible to zero inflation.
- (3) Normalizing pool-based size factors (i.e., summed expression values) against an average reference.
- (4) Deconvolving the pool-based size factors into the size factors for its constituent cells to adjust for cell-specific biases.

The scran normalization method is publicly available using the `computeSumFactors` function in the “scran” package, version 1.6.6 on Bioconductor (see “Relevant Websites section”).

SCnorm

This method is based on the observation that scRNA-seq data shows systematic biases in the relationship between transcript-specific expression and sequencing depth – referred to as count-depth relationship – that cannot be adjusted by a single global scale factor common to all genes in a cell. Accordingly, normalization methods based upon global scale factors can contribute to overcorrection of weakly/moderately expressed genes and undernormalization of highly expressed genes (Bacher *et al.*, 2017).

To address this, SCnorm performs the following key steps:

- (1) Estimating the dependence of transcript expression on sequencing depth for every gene using quantile regression.
- (2) Grouping genes with similar dependence.
- (3) Estimating scale factors within each group through a second quantile regression.
- (4) Providing normalized estimates of expressions by performing within-group adjustment for sequencing depth using the estimated scale factors.

The SCnorm normalization is publicly available as an R package “SCnorm” version 1.0.0 on Bioconductor (see “Relevant Websites section”).

Conclusions

Transcriptomics has paved the way for a comprehensive understanding of how genes are expressed and interconnected. Over the last three decades, methodological breakthroughs have repeatedly revolutionized transcriptome profiling and redefined what is possible to investigate. Integration of transcriptomic data with other omics is giving an increasingly integrated view of cellular complexities facilitating holistic approaches to biomedical research (Lowe *et al.*, 2017b).

Normalization of transcriptomic data is an essential preprocessing step aimed at correcting unwanted biological effects and technical noises prior to any downstream analysis. Normalization methods shall be chosen according to the undertaken technology and can be platform-specific. While there is no consensus on the best normalization methods across different transcriptomic technologies, several efforts have been taken to develop additional robust and effective normalization techniques and to systematically assess their performance on individual data sets.

Author Contributions

FV designed and supervised the study. FV, HD, and HAR wrote and revised the article. FV prepared the final version of the article. HD and HAR generated Fig. 1 and FV generated Figs. 2–4. All authors have read and approved the final version of the article.

Differential Expression From Microarray and RNA-seq Experiments

Marc Delord, Université Paris Diderot-Paris 7, Sorbone Paris Cité, Paris, France

Introduction

Gene transcription is the process by which genes are copied into different types of RNAs, such as messenger RNA (mRNA) leading to the synthesis of proteins through translation, or noncoding RNA such as micro RNA (mRNA), transfer RNA (tRNA), or ribosomal RNA (rRNA) (Fig. 3) (Bolsover *et al.*, 1997). In the past decades, various methods have been developed for quantifying mRNA from biological samples at different scale, including quantitative reverse transcription-polymerase chain reaction (qRT-PCR) (Heid *et al.*, 1996), serial analyses of gene expression (SAGE) (Velculescu *et al.*, 1995), hybridization of cDNA (Schena *et al.*, 1995) or oligonucleotide chips (Lockhart *et al.*, 1996), and high-throughput RNA sequencing (RNA-seq) (Nagalakshmi *et al.*, 2008; Holt and Jones, 2008; Wang *et al.*, 2009) (Fig. 1).

Differential expression refers to the supervised analysis of gene expression data. This definition supposes therefore that expression of one or more genes has been quantified in various experimental conditions, or with respect to a quantitative trait or a censored time to event outcome. In large scale gene profiling experiments, the expression of thousands of genes or transcribed regions is quantified from relatively few biological samples. This situation where the number of measured items far exceeds the sample size is known as the *large p small n paradigm* (West, 2003; Kosorok and Ma, 2007) as it reverses the standard frequentist paradigm in which experiments are designed and powered in order to highlight a meaningful difference of one or few response variables observed in various experimental conditions.

Gene profiling experiments are therefore relatively underpowered and can be considered numerically as ill-posed problems, the uniqueness and stability of results being not guaranteed (Kabanikhin, 2008; Philippe, 2008). Besides, allowances that have to be made for the amount of multiple testing by the control of the type I error rate (familywise error rate or false discovery rate (FDR) (Benjamini and Hochberg, 1995; Dudoit *et al.*, 2003)) also reduce the statistical power available for detecting differential expression at the gene level. Differential analysis of gene expression is therefore a challenging task from a statistical point of view.

The challenge of the analysis of gene expression data and more generally high-throughput genomic data has favored the development and the spreading of statistical methods and procedures that are able to take advantage of the massively parallel structure of genomic data. By *borrowing strength* across features (Morris, 1983; Kerr and Churchill, 2001; Newton *et al.*, 2001; Smyth, 2004), the so-called empirical Bayes approaches (Efron and Morris, 1973; Efron and Morris, 1977; Carlin and Louis, 1996) outperform the naive feature-by-feature estimations. The idea behind these methods stems from the pioneering work of Stein Charles, (1955) who shows that the simultaneous estimate of multiple parameters is more accurate on average than sequential optimal estimations.

Fig. 1 Gene expression: Transcription and translation are the two steps of gene expression. During transcription, DNA is used as a template by RNA polymerase (green) to produce a pre-mRNA transcript. The pre-mRNA is then processed into a mature messenger RNA molecule (mRNA) finally translated into a protein (polypeptide).

However, having a better estimator on average does not guarantee that a particular single estimate is more accurate. Therefore, analysts and practitioners have to keep in mind that the aim of gene profiling experiments is less to test for a prespecified hypothesis on the expression of single genes than to set expression signatures associated to particular experimental conditions, cell types, tumors, or clinical outcomes. It represents therefore a shift from an hypothesis testing paradigm to an hypothesis generating paradigm (Biesecker, 2013) where a relevant task would be to prioritize genes with respect to some statistical summaries that are not directly used to assess for departure from the null hypothesis (that is no association between expression of a given gene and a covariate) in favor of the alternative hypothesis of differential expression (Noma *et al.*, 2010).

Since the emergence of high-throughput gene profiling technologies such as the serial analysis of gene expression (SAGE) (Velculescu *et al.*, 1995), cDNA microarrays (Schena *et al.*, 1995; Lennon and Lehrach, 1991) and oligonucleotide microarrays (Lockhart *et al.*, 1996), or RNA sequencing (RNA-seq) (Holt and Jones, 2008; Wang *et al.*, 2009; Wilhelm *et al.*, 2008; Mortazavi *et al.*, 2008; Cloonan *et al.*, 2008; Sultan *et al.*, 2008), the consensus that gene expression data should be analyzed at once in the framework of empirical Bayes procedures has emerged (Cui and Churchill, 2003; Sonesson and Delorenzi, 2013). This idea has been translated into numerous statistical libraries allowing to perform differential analysis of gene expression data in computational frameworks such as the *R Language and Environment for Statistical Computing* (R. Core Team, 2017) and the *Bioconductor* project (Gentleman *et al.*, 2004; Huber *et al.*, 2015).

Though differential expression analysis refers preferentially to methods and tools developed in the context of gene expression data arising from microarray or RNA-seq, the paradigm of differential expression analysis extends to the analysis of data arising from any massively parallelized technologies producing intensity measurements such as array-based proteomics methods (MacBeath and Schreiber, 2000) or overdispersed count data such as ChIP-Seq data (Robertson *et al.*, 2007) or 4C (Simonis *et al.*, 2006).

This article is organized as follows: Section “Background” gives an overview of gene profiling experiments and describes principles of hybridization- (microarrays) and sequencing-based (RNA-seq) approaches. Section “Differential Expression” introduces differential expression of gene profiling experiments in the framework of microarrays (first subsection) and in the framework of RNA-seq experiments (second subsection). The Section “Conclusion” proposes a summary and some concluding remarks.

Background

Transcriptomics refers to the mapping and quantification of the sum of all transcripts present in particular cell type or tissue (de la Grange *et al.*, 2010; Aguet *et al.*, 2017), in determined conditions (Hughes *et al.*, 2000), development stages (Graveley *et al.*, 2011), cell cycle (Cho *et al.*, 1998), treatments or states of health (Lenz *et al.*, 2008). Gene expression microarrays (Schena *et al.*, 1995; Lockhart *et al.*, 1996) and deep sequencing of RNA (RNA-seq) (Nagalakshmi *et al.*, 2008; Holt and Jones, 2008; Wang *et al.*, 2009) are the two dominant high-throughput technologies used to quantify transcripts at the genome-wide scale. These techniques allow to capture a snapshot of the transcriptional activity of a sample of cells or a tissue at reasonable costs and labor (Holt and Jones, 2008; Wang *et al.*, 2009; Aguet *et al.*, 2017; Heller, 2002; Lowe *et al.*, 2017) (Figs. 2 and 4).

Differential expression is arguably one of the most common uses of gene expression profiling experiments (Sonesson and Delorenzi, 2013; Pan, 2002). Its application includes the molecular characterization of tissues (Mortazavi *et al.*, 2008; Aguet *et al.*, 2017), the classification and prediction of diseases subtypes (Golub, 1999; Perou *et al.*, 2000), the development of prognostic

Fig. 2 Reference of gene expression profiling methods over time: Number of published papers referenced in pubmed referring to “microarray,” “microarray + gene expression or gene profiling,” “RNA-seq,” “RNA-seq + gene expression or gene profiling” over time in their title or abstract.

tools (van't Veer *et al.*, 2002; Paik *et al.*, 2004) and diagnostic tools (Spira *et al.*, 2007; Griffith *et al.*, 2006), or the functional annotation of gene through the analysis of clusters of genes associated to developmental stages (Graveley *et al.*, 2011; Bassett *et al.*, 1999) or diseases subtypes (Hughes *et al.*, 2000; Figueroa *et al.*, 2013). In drug discovery, differential expression analysis allows to validate candidate targets and get further insight on the functional connections among diseases and drug action at the transcriptome level (Hughes *et al.*, 2000; Lamb *et al.*, 2006). Gene expression profiling and differential expression are also powerful tools to characterize at the molecular level biological systems perturbed by genes knock-out or mutations (Hughes *et al.*, 2000).

Of note, although the molecular classification and characterization of oncogenic subtypes have represented an early success of gene profiling experiments (Golub, 1999; van't Veer *et al.*, 2002), their clinical utility remain unclear (Edén *et al.*, 2004; Bonastre *et al.*, 2014; Blok *et al.*, 2018). Indeed, assessment of molecular signatures for personalizing patient care is pursued preferentially using dedicated prospective clinical trials (Simon and Wang, 2006; Delord, 2015; Tajik *et al.*, 2013) in which the marginal contribution of molecular signatures is assessed over gold standards of clinical care. In practice, however, it is frequent that the information provided by molecular profiling of tumors overlaps with standard phenotypic or anatomopathological biomarkers (Edén *et al.*, 2004; Simon *et al.*, 2009), making it therefore unlikely to provide an improvement of the clinical practice. Also, when gene expression signatures are found to be clinically relevant, cost-effectiveness analyses are needed to evaluate their utility in the daily clinical practice (Bonastre *et al.*, 2014; Blok *et al.*, 2018).

Gene expression profiling technologies are based on the following principles: in the microarrays approach (Schena *et al.*, 1995; Lockhart *et al.*, 1996; Lennon and Lehrach, 1991; Heller, 2002), gene expression is estimated via hybridization of transcript cDNA to an array of predefined complementary probes spotted or synthesized at determined locations. On the other hand, in the sequencing approach, transcripts cDNA are sequenced using high-throughput sequencing technologies (Holt and Jones, 2008; Wang *et al.*, 2009) and quantification is derived from counts of sequences associated (in silico) to a given transcript (Fig. 3) (Wang *et al.*, 2009).

Fig. 3 Differential gene expression profiling using two-color microarrays (B), one-color microarray (C), and RNA-seq (D): In the proposed experiment, differential expression is assessed between biological samples 1 and 2. mRNA is extracted from biological samples and reverse transcribed to double strand cDNA (A). In the two-color microarray approach (B), single strand cDNA from both samples are labeled using different dyes, pooled, and incubated for hybridization into a single microarray. In the one-color microarray approach (C), single strand cDNA is labeled using the same dye and incubated for hybridization into separate oligonucleotide microarrays. Once hybridization is completed, microarrays are scanned and row expression values are derived from intensity of fluorescence for each color and each probe. In the RNA sequencing procedure (D), mRNA is reverse transcribed and amplified to cDNA followed by deep sequencing. Resulting short reads are aligned in silico and quantified.

Fig. 4 Estimated cost per genome: Estimation includes global production costs such as labor, utilities, reagents and consumables, sequencing instruments, informatics activities, and indirect costs such as general laboratory supplies, etc. Data from the National Human Genome Research Institute (NHGRI) Genome Sequencing Program (GSP) (<https://www.genome.gov/27541954/dna-sequencing-costs-data/NationalHumanGenomeResearchInstitute>).

Since the publications of the first RNA sequencing studies using high-throughput sequencing platforms in 2008 (Nagalakshmi *et al.*, 2008; Wilhelm *et al.*, 2008; Mortazavi *et al.*, 2008; Cloonan *et al.*, 2008; Sultan *et al.*, 2008; Denoeud *et al.*, 2008), this approach has become widespread (Fig. 2). This evolution, which is due to the effectiveness of this technique (higher sensitivity and dynamic range and lower technical variations (Griffith *et al.*, 2010)), has been also favored by the dramatic decrease in sequencing costs (Fig. 4) (Holt and Jones, 2008; Wang *et al.*, 2009), and by the development of bioinformatic tools and dedicated statistical software (Soneson and Delorenzi, 2013; Huber *et al.*, 2015; Oshlack *et al.*, 2010). Nevertheless, the use of microarrays remains a powerful tool to assess the expression level of large sets of genes in the biological and clinical setting (Oshlack *et al.*, 2010). The use of microarrays is also favored by the availability of numerous preprocessing and normalizing procedures as well as an established theoretical and computational framework (Smyth, 2004; Cui and Churchill, 2003; R. Core Team, 2017; Huber *et al.*, 2015; Li and Wong, 2001; Lönnstedt and Speed, 2002; Efron and Tibshirani, 2002; Irizarry *et al.*, 2003; Storey *et al.*, 2007; Ritchie *et al.*, 2015).

The Microarray Approach to Gene Expression Profiling

In the late 1990s and into the 2000s, advances in genome sequencing of multiple species have provided the necessary information to produce microarrays allowing therefore to quantify the expression of large sets of genes (Brown and Botstein, 1999). Two microarray technologies have been widely used: the two-color approach (Schena *et al.*, 1995), and the one-color (or single channel) approach (Lockhart *et al.*, 1996). In two-color microarrays, two samples of transcript cDNA are labeled with different fluorophores and mixed. The resulting solution is incubated for competitive hybridization into a single microarray (Fig. 2(A) and (B)). In one-color microarrays, transcript cDNA from a single sample is labeled and incubated for hybridization into a single microarray (Fig. 2(A) and (C)).

While the two-color approach produces ratios of fluorescence intensities that reflect the relative abundance of labeled transcripts from the samples and the reference, the one-color approach yields absolute fluorescence intensities. In both cases, intensity of fluorescence is assumed to be related to the abundance of transcripts extracted from a biological sample hybridized to a microarray.

Dedicated studies have investigated the validity and equivalence of both methods (Patterson *et al.*, 2006; Larkin *et al.*, 2005; Oberthuer *et al.*, 2010) and have concluded in an overall good concordance between them. Of note, due to advantages in terms of logistics, simpler experimental designs, and data interpretation, the one-color oligonucleotide microarray has progressively supplanted the two-color spotted microarray in the 2000s (Bumgarner, 2013).

However, despite the successful use of microarrays in gene expression profiling experiments, this technology presents a number of inherent limitations such as dye-based detection issues, cross-hybridization artifacts, and a range of detection limited by a high background level and saturation of signals (Okoniewski and Miller, 2006). The hybridization-based approach relies also on prior knowledge on organisms under study including the coverage of all possible genes and associate isoforms, noncoding RNAs, and splicing events. Microarray may also produce poor results in profiling genes from highly variables genomes such as those from bacteria (Bumgarner, 2013). Advances of high-throughput DNA sequencing technologies in the mid-2000s have allowed to overcome previous constraints associated to the sequencing-based approach and provided an effective alternative to the hybridization-based approach to gene profiling experiments.

The Sequencing Approach to Gene Expression Profiling

The sequencing approach has emerged as an indirect application of DNA sequencing technologies (Velculescu *et al.*, 1995; Holt and Jones, 2008; Wang *et al.*, 2009). The SAGE (Velculescu *et al.*, 1995) proposed in the 1990s is one of the first successful attempts for quantifying expression of multiple genes in a single experiment. This approach uses Sanger sequencing and provides *digital* gene expression through the following steps:

- Mature mRNA is reverse transcribed into cDNA,
- cDNA is fragmented into 11 base-pair (bp) fragments (*tags*) using restriction enzymes,
- Tags are concatenated into long strands of cDNA and sequenced using Sanger technology,
- The resulting sequence tags are aligned along the reference genome and identify corresponding genes,
- Gene expression can be derived from counts of associated tags.

Differential gene expression can then be performed by using the SAGE approach on biological samples from various experimental conditions.

However, SAGE and other tag-based approaches that are based on traditional Sanger sequencing technologies are expensive and lack specificity as a significant proportion of tags cannot be unambiguously mapped to the reference genome. Following the advent of high-throughput sequencing technologies, such as 454 technology allowing to sequence transcripts of random length (from 25 to 300 base pair (bp)) the principle of digital gene expression has evolved and allowed the quantification of transcripts by sequencing (RNA-seq) through the following steps:

- mRNA is extracted from a biological sample, fragmented, and reverse transcribed into a library of double strand cDNA,
- Double strand cDNA is sequenced using high-throughput sequencing technologies,
- Resulting reads are aligned to the reference genome and identify corresponding genes,
- Gene expression is derived from counts of associated reads.

Different options are available at each step, for instance the cDNA library can be amplified by PCR to allow sequencing of low amounts of input RNA (Shanker *et al.*, 2015), high-throughput sequencing of cDNA can be performed using one of the different technologies mentioned above, from one end (single-end) or both ends (pair-end). However, the single-end sequencing is faster, cheaper, and sufficient for simple gene profiling experiments and differential gene expression analysis and is therefore recommended for these applications. Each biological sample produces up to 10^9 short sequences, which are associated to quality scores and listed in the fastq format in so-called fastq files. A human transcriptome can be adequately captured with approximately 30 million 100 bp reads (Hart *et al.*, 2013; Conesa *et al.*, 2016), corresponding to 1.8 gigabytes compressed fastq files.

Preprocessing of RNA-seq data

Prior to differential expression analysis using RNA-seq experiments the following three steps are needed: (1) quality control of raw reads, (2) reads alignment, and (3) read counts or transcript quantification (Fig. 5).

Quality control: Fastq files contain the list of raw reads sequence data and associated quality scores. Tools such as FastQC (Babraham Bioinformatics - FastQC A, 2017) (Illumina platform) or NGSQC (Dai *et al.*, 2010) (any platform) allow dealing with sequencing errors such as duplicated reads, GC and k-mers content, or presence of adapters. A common trait to all sequencing platforms is to produce reads whose quality decreases toward their 3' end. Software such as FASTX-Toolkit (Hannon lab, 2010) or Trimmomatic (Bolger *et al.*, 2014) can be used to discard low-quality reads and trim low-quality bases. Prior to the mapping step, the filtering out of poor quality reads allows to prevent for mismatches and downstream errors and bias.

Alignment: Different options are available for the alignment step: if no reference genome is available or is incomplete, the *de novo* transcript reconstitution is required using tools such as SOAPdenovo-Trans (Xie *et al.*, 2014), Oases (Schulz *et al.*, 2012), trans-ABYSS (Grabherr *et al.*, 2011), or Trinity (Haas *et al.*, 2013) (for a comprehensive evaluation of *de novo* transcriptome programs in differential gene expression analysis see Wang and Grubbskov (2016)). When a reference genome is available, the possible options are mapping to the genome or mapping to the transcriptome. Mapping to the genome requires the use of mapper allowing for gaps to account for (alternative) splice junctions. This approach allows the discovery of novel transcripts, gene

Fig. 5 RNA-seq workflow prior to differential expression analysis.

isoforms, or fusion transcripts using tools such as Tophat (Trapnell *et al.*, 2009; Kim *et al.*, 2013), MapSplice (Wang *et al.*, 2010), STAR (Dobin *et al.*, 2013), or OSA (Hu *et al.*, 2012) (for a review of genome-based sequence reads mappers, see Xie *et al.* (2014)). Finally, if a comprehensively annotated transcriptome is available, sequence reads alignment can be performed using an unspliced mapper such as Bowtie (Langmead *et al.*, 2009) allowing for gene identification and quantification simultaneously.

Transcript quantification: Once a genomic position is allocated to as many sequence reads as possible the next task is the quantification of transcripts. Depending on a chosen biologically meaningful unit, i.e., exon, transcript, or gene, this task is performed following specific sets of rules and results in a table of read counts. Quantification tools include HTSeq-count (Anders *et al.*, 2015), featureCounts (Liao *et al.*, 2014), or Cufflinks (Trapnell *et al.*, 2010). For instance, the basic strategy proposed by HTSeq is to account for a given transcript all read mapping unambiguously to the corresponding location while discarding multimapping reads. On the other hand, the Cufflinks strategy is to allocate ambiguous reads to the most probable transcribed or gene.

From fastq files containing reads for each sample to gene quantification, many options are therefore available at each step. The choice of an analysis pipeline will depend on subjective preferences of practitioners and can result in quite different expression level estimated in subsets of genes (Fonseca *et al.*, 2014). It can be noted also that other factors, such as overall sequencing coverage or gene characteristics (length or GC-content), may also affect gene profiling results (Fonseca *et al.*, 2014). When prior transcriptome knowledge is required, a paired strand-specific sequencing strategy is recommended as it provides more information to compute a *de novo* assembly of the transcriptome (Haas *et al.*, 2013). However, when a reference genome or transcriptome is available, this strategy does not improve significantly gene expression estimates (Fonseca *et al.*, 2014). Different studies have reported overall good performance of gapped mappers including Tophat, STAR, and OSA (Hu *et al.*, 2012; Fonseca *et al.*, 2014) and suggest that any of these tools could be used in the context of gene profiling experiments. On the other hand, Fonseca *et al.* (2014) have reported the critical role played by quantification methods in numerous pipelines and the good performance of the simple counting strategy of HTSeq over more sophisticated tools such as Cufflinks or Flux-Capacitor.

Differential Expression

Microarrays

Microarray experiments provide indirect estimates of gene expression through the measurement of fluorescent *spots* supposed to be related to the abundance of labeled transcripts hybridized at given positions on an array.

On a two-color microarray, where mRNA samples are hybridized against a common reference using red and green dyes respectively, relative expression values are computed as a log-ratio of fluorescence intensities:

$$M_g = \log_2(R_g) - \log_2(G_g), \quad g = 1, \dots, N \quad (1)$$

where R_g and G_g are respectively the red and green intensities for gene g , and N is the total number of genes. Most of the time, the scatter plot of $M_g = \log_2(R_g) - \log_2(G_g)$ versus $A = (\log_2(R_g) + \log_2(G_g))/2$, $g = 1, \dots, N$ (MA plots) reveals a systematic relation between log-ratios versus mean intensities. Making the assumption that most of the genes share the same expression between samples, this effect can therefore be considered as a dyes bias and corrected for using a method such as the locally weighted scatterplot smoothing (LOWESS) regression of Cleveland (1979). Of note, the assumption of equal expression of the majority of genes between biological samples can be verified by conducting a dye-swap experiment. In this experiment, the two-color procedure is duplicated from the same biological samples except for dyes, which are inverted. Dyes swap experiments allow therefore to verify that the relation between log-ratios and the mean intensity is a dye artifact that has to be corrected for.

The assumption of equal global expression level between biological samples allows also to consider that variations in global intensity between microarrays are technical artifacts that should be corrected for by scaling expression level between microarrays using a method such as quantile normalization. Once log ratios have been properly corrected for within-sample (dyes bias) and between-sample artifacts, differential expression related to treatment, conditions, or phenotype of interest can be conducted.

For one-color microarrays, a single vector of log-intensities is derived from each microarray. Summarization and normalization of intensities between arrays are usually computed following methods such as model based expression index (MBEI) implemented in dChip (Li and Wong, 2001), robust multichip average (RMA) (Irizarry *et al.*, 2003) or RMA using sequence information (GCRMA) (Wu *et al.*, 2004). These routines produce expression values suitable for further analysis. These procedures are also based on the assumption of equal global expression level between biological samples.

We introduce now differential expression analysis using data arising from a microarray experiment in a simple two-condition experimental design. In this experiment the expression of N genes was estimated from n_1 wild type samples and n_2 muted samples, using single channel microarrays. We assume that expression values were summarized and normalized between arrays and represented in a $N \times (n = n_1 + n_2)$ matrix (Y). The response vector for gene g (i.e., the estimated expression of gene g measured in the n biological samples) is $y_g = (y_{g,1}^{wt}, \dots, y_{g,n_1}^{wt}, y_{g,1}^m, \dots, y_{g,n_2}^m)$. We compute also for gene g , $\bar{y}_{wt,g}$ and $\bar{y}_{m,g}$ the sample mean of expression, and $s_{wt,g}$ and $s_{m,g}$ the sample standard deviation in wild type and mutates samples respectively. From the above we obtain the difference in mean log-expression or log fold change for gene g :

$$D_g = \bar{y}_{m,g} - \bar{y}_{wt,g}$$

and the sample variance:

$$s_g^2 = \frac{(n_1 - 1)s_{wt,g}^2 + (n_2 - 1)s_{m,g}^2}{n_1 + n_2 - 2}$$

Using these simple quantities, different procedures have been used for identifying differentially expressed genes in microarray experiments. Their basic principle is to rank genes according to some relevant statistic and to consider genes whose statistics stand above an arbitrary chosen cut-off as differentially expressed (Noma *et al.*, 2010; Cui and Churchill, 2003; Draghici, 2002). The log fold change has been used as a simple criterion to rank genes in early gene expression profiling studies (Schena *et al.*, 1995), however as its computation does not integrate a measure of the variability observed in each group, this statistic lacks confidence and therefore is not recommended in practice (Cui and Churchill, 2003).

The *signal to noise ratio* integrates a measure of the observed variance:

$$\frac{D_g}{s_{wt,g} + s_{m,g}}$$

Though this statistic allows to rank genes according to their differential expression, it is not related to a standard probability distribution and therefore does not allow to compute a type I error rate when testing the hypothesis of differential expression: $D_g \neq 0$.

Despite small sample size, the need for controlling the type I error rate has led to use of statistics following tabulated distributions such as the *t*-statistic. Assuming normality of log-expression values and equal variance between groups, under H_0 (i.e., $D_g = 0$), the t_g statistic:

$$\frac{D_g}{s_g \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}}$$

follows a Student distribution with $(n_1 + n_2 - 2)$ degrees of freedom and can be approximated by a standard normal distribution if samples size are large enough. This probabilist framework allows to compute a *p*-value:

$$2 \times P(t_{(n_1+n_2-2)} > |t_g|)$$

which can be interpreted as a measure of the evidence against H_0 given the data. If the assumption of equal variance between groups does not stand, the Welch *t*-test can be used by computing the statistic:

$$\frac{D_g}{\sqrt{\frac{s_{wt,g}^2}{n_1} + \frac{s_{m,g}^2}{n_2}}}$$

which follows a Student distribution with modified degrees of freedom if $D_g = 0$ (Welch, 1947).

The *t*-statistic presents appealing properties as it allows to rank genes in order of evidence against H_0 (Smyth, 2004; Noma *et al.*, 2010) and to choose a *p*-value cutoff associated to a desired overall type I error rate. However, the ranking obtain by the *t*-statistic would not be optimal if the sample variance is not reliable due to the few degrees of freedom available. Underestimated sample variances would lead to large values of the *t*-statistics and high rate of false positives, while overestimated sample variances would lead to low values of the *t*-statistics and therefore high rate of false negative, i.e., a loss of power.

To overcome this difficulty, the assumption of equal variance across genes has been proposed (Arfin *et al.*, 2000). This assumption leads to use the empirical mean of the sample variance estimated from all genes:

$$s^2 = \frac{1}{N} \sum_{i=1}^N s_i^2$$

This average pooled variance has therefore $N \times (n_1 + n_2 - 2)$ degrees of freedom, and the denominator of all *t* statistics becomes $s \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}$. The resulting test statistics can be compared to a standard normal variable to assess the probability of observed expression values under H_0 . This approach suffers however from the following two major restrictions: (1) it relies on highly unlikely assumptions and (2) it is equivalent to a log fold change ranking procedure and shares the same limitations, it is therefore not recommended to assess differential expression.

To prevent erratic values of the *t*-statistic that may be due to unreliable estimates of the sample variance Tusher *et al.* (2001) have proposed to add a small positive constant to the denominator of the *t*-statistic. In practice the constant can be derived as the 90th percentile of the standard deviation of all genes (Efron *et al.*, 2000). The statistical significance is then assessed using a permutation procedure.

Alternative approaches have been proposed in which advantage is taken from the parallel structure of the data while gene-specific variance is also considered (Smyth, 2004; Lönnstedt and Speed, 2002; Baldi and Long, 2001; Wright and Simon, 2003).

The regularized *t*-statistic proposed by Baldi and Long (2001) can be presented as follows: In a Bayesian framework, prior information on the gene-specific variance is obtained from d_0 genes sharing similar intensity (σ_0^2). The *Bayesian adjusted denominator* of the regularized *t*-statistic is computed as a weighted average of the gene-specific sample standard error (s_g) and σ_0 . The regularize *t*-statistic is:

$$\tilde{t}_g = \frac{D_g}{\tilde{s} \sqrt{\frac{1}{n_1} + \frac{1}{n_2}}}$$

with

$$\tilde{s}^2 = \frac{(n-1)s_g^2 + d_0\sigma_0^2}{(n-2) + d_0}$$

The *moderated* t -statistic of Smyth (2004) is similar to the Baldi and Long statistic but with a prior information on the gene-specific variance, which is derived from the proportion (p_0) of genes assumed to be differentially expressed between conditions where p_0 is estimated from the data.

In both cases, a background pooled variance σ_0^2 on d_0 degrees of freedom is estimated from the data and used as prior information on the gene-specific sample variance to moderate the gene-specific sample variance. The resulting modified t -statistic follows a Student distribution with $(n-2) + d_0$ degrees of freedom under H_0 . That is, an extra d_0 degrees of freedom are considered for $\tilde{t}_g$ as compared to the $n-2$ degrees of freedom used for the classical gene-wise t -statistic t_g .

These methods are part of empirical Bayes approaches as prior information is derived from the whole dataset. The added degrees of freedom used to infer from individual genes is borrowed from all genes involved in the experiment. Individual sample variances are therefore shrunk toward a common variance and result in a far more stable inference, especially when the sample size is small, and with overall gain in statistical power (Smyth, 2004). Finally, even in cases where the normality assumption does not hold, empirical Bayes test statistics lead to more accurate ranking of genes as compared to gene-wise ranking procedures.

It is worth mentioning also the B statistic of Lönnstedt and Speed (2002), which is an empirical Bayes log posterior odds-ratio of differential expression. The numerator of the B statistic is the probability that a given gene is differentially expressed, while the denominator is the probability that the gene is not differentially expressed. Both quantities are posterior probabilities combining gene-specific information, and information derived from all other genes, producing therefore more stable inference and overall more powerful procedure than the naive gene-wise approach.

Review of tests and procedures used for differential expression using microarrays can be found in Pan (2002) and Cui and Churchill (2003). In practice, the approach proposed by Smyth (2004) is the most widely used. It is implemented in the R library *limma* (Ritchie et al., 2015) which provides also facilities for reading and normalizing data from many microarray technologies including two-color microarrays and single-channel oligonucleotide platforms such as Affymetrix microarrays. It allows also to handle complex experimental designs and multiple comparison experiments in the framework of linear models.

RNA-seq

Counts resulting from RNA-seq experiments are supposed to be linked proportionally to the number of mRNA copies extracted from a biological sample and yield therefore a direct estimation of the transcriptional activity of cells from biological samples under study. However, as read counts not only depend on gene expression levels but also on length of transcripts (Oshlack and Wakefield, 2009) and overall coverage level, (Robinson and Oshlack, 2010) an appropriate normalization procedure is needed before differential expression analysis. This situation is illustrated by the RNA-seq experiment of Fig. 6(A) where gene A is assumed to be expressed twice as much as gene B in both samples. Gene A is also assumed to have the same expression between samples. Genes A and B have length $l_A=2$ and $l_B=3$ respectively, and total read counts in sample 1 and 2 are $N_1=7$ and $N_2=14$ respectively. Y_{ij} denotes read count of gene i in sample j . Computing fold-change of gene expression using raw read counts gives the following results:

- Fold change of gene expression between genes A and B in sample 1:

$$\frac{Y_{A,1}}{Y_{B,1}} = \frac{3}{4} = 0.75$$

Fig. 6 The need for normalization procedure in differential expression analysis using RNA-seq data.

- Fold change of gene expression between conditions 2 and 1 for gene B:

$$\frac{Y_{B,2}}{Y_{B,1}} = \frac{6}{3} = 2$$

which does not reflect the *true* relative expression level of gene A versus gene B. This discrepancy is due to differences in gene lengths within samples and overall coverage between samples. Therefore, alike for the hybridization approach, the need arises for normalization procedures to adjust for within-sample and/or between-sample characteristics prior to differential analysis in RNA-seq experiments (Bullard *et al.*, 2010).

Within-Sample Normalization

Taking into account the gene length as a normalization factor for the within-sample comparison of gene expression gives the expected results:

$$\frac{\frac{Y_{A,1}}{l_A}}{\frac{Y_{B,1}}{l_B}} = \frac{4/2}{3/3} = 2$$

In practice, for within-sample normalization of RNA-seq experiments, different metrics of gene expression have been proposed among which are RPKM (reads per kilobase of exon per million mapped reads) (Mortazavi *et al.*, 2008), FPKM (replace reads by fragments) (Grabherr *et al.*, 2011; Trapnell *et al.*, 2010), and TPM (transcript per million) (Li *et al.*, 2010), all of which are essentially identical.

To compute these quantities, we can obtain first the count per million (CPM) for gene i (Law *et al.*, 2014):

$$\text{CPM}_i = \frac{Y_i}{N} \cdot 10^6 \quad (2)$$

where Y_i is the read count for gene i and N the total number of reads. This quantity represents simply the number of reads from gene i per million reads.

RPKM and FPKM are analogous quantities. FPKM is a more generic quantity as it explicitly accommodates data from single- or paired-end RNA-seq experiments. It is equivalent to RPKM in single-end RNA-seq experiments.

FPKM _{i} is proportional to CPM _{i} divided by the length of gene i (l_i):

$$\text{FPKM}_i = \frac{\text{CPM}_i}{l_i} \cdot 10^3 = \frac{Y_i}{l_i N} \cdot 10^9 \quad (3)$$

Finally, to obtain TPM _{i} , transcript i reads count needs to be normalized by length of gene i to get the rate of reads of type i , then to adjust for the total number of reads, divide rate i by the sum of all rates and scale to get a *per million reads* quantity:

$$\text{TPM}_i = \frac{Y_i}{l_i} \cdot \left(\frac{1}{\sum_j \frac{Y_j}{l_j}} \right) \cdot 10^6 \quad (4)$$

Remarks

- As shown in (3) the FPKM metric can be obtained by dividing the rate of transcript i by the total number of reads N and multiplying the result by 10^9 . Using this formulation in (4) the TPM metric can be expressed as (Pachter, 2011):

$$\begin{aligned} \text{TPM}_i &= \frac{Y_i}{l_i N} \cdot 10^9 \cdot \left(\frac{1}{\sum_j \frac{Y_j}{l_j N} \cdot 10^9} \right) \cdot 10^6 \\ &= \frac{\text{FPKM}_i}{\sum_j \text{FPKM}_j} \cdot 10^6 \end{aligned}$$

Basically, both FPKM and TPM give the number of reads per base of feature i , per $N/10^6$ million reads in the FPKM metric and per million reads in the TPM metric. TPM is therefore more generic than FPKM (or RPKM) and its use is therefore recommended (Wagner *et al.*, 2012).

- The number of reads for a given gene depends also on the overall coverage and therefore the number of reads in a given sample. Though TPM or FPKM take into account the total number of reads, the use of these metrics would allow for comparison between samples, only if samples show similar expression profiles such as in the experiment shown in Fig. 6(A):

$$\frac{\frac{Y_{B,2}}{l_B N_2}}{\frac{Y_{B,1}}{l_B N_1}} = \frac{\frac{6}{3 \times 14}}{\frac{3}{3 \times 7}} = 1$$

However, this assumption is highly unlikely in any RNA-seq experiments. Fig. 6(B) shows a more realistic RNA-seq experiment where expression profiles differ between samples. Total read counts in samples 1 and 2 are $N_1^* = 18$ and $N_2^* = 20$ respectively. Differential expression of gene B between samples using FPKM gives a misleading result:

$$\frac{\frac{Y_{B,2}}{L_B N_2^*}}{\frac{Y_{B,1}}{L_B N_1^*}} = \frac{\frac{6}{3 \times 20}}{\frac{3}{3 \times 18}} = 1.8$$

This simple example illustrates the need for normalizing procedures allowing to estimate the *true* differences in overall coverage between samples. It suggests also that a good normalizing procedure between samples should reduce as much as possible the influence of differentially expressed genes as reads from these genes may represent a significant proportion of the total number of reads.

Between Sample Normalization

Recall that the goal of differential expression is to estimate ratios of gene expression between two or more experimental conditions. Using the sampling framework of Robinson and Oshlack (2010), in RNA-seq experiments, the expected count of reads associated to transcript i in condition k is assumed to be related to the expected number of transcript i per cell ($\mu_{i,k}$), the length of gene i ($l_{i,k}$), the total number of reads (N_k), and the length of transcriptome under study (S_k) in condition k :

$$E[C_{i,k}] = \frac{\mu_{i,k} l_i}{S_k} N_k \quad (5)$$

with

$$S_k = \sum_i \mu_{i,k} l_i$$

Using the delta method, it can be shown from expression (5) (Robinson and Oshlack, 2010) that the expected value of the ratio of read counts between conditions 1 and 2 for gene i is:

$$E\left[\frac{Y_{i,2}}{Y_{i,1}}\right] = \frac{\mu_{i,2} S_1 N_2}{\mu_{i,1} S_2 N_1} \quad (6)$$

Expression (6) shows clearly that for gene i , the expected fold change of read counts between conditions 1 and 2 depends on the ratio of the expected number of transcripts ($\mu_{i,2}/\mu_{i,1}$), the relative overall coverage (N_2/N_1), and the relative size of transcriptomes under study (S_1/S_2), which can vary drastically between conditions (Robinson and Oshlack, 2010). An appropriate normalization procedure would therefore aim at estimating Y_1^* and Y_2^* such that $E[Y_{i,1}^*/Y_{i,2}^*] = \mu_{i,1}/\mu_{i,2}$.

Among the many approaches available for between-sample normalization (Dillies *et al.*, 2013), three can be used to deal with both bias due to transcriptome size and sequencing depth: the trimmed mean of M -values procedure (TMM) (Robinson and Oshlack, 2010) implemented in the edgeR R library (Robinson *et al.*, 2010), the relative log-expression procedure (RLE) implemented in the DESeq2 R library (Anders and Huber, 2010; Anders *et al.*, 2013; Love *et al.*, 2014), and the mean ratio normalization procedure (MRN) (Maza *et al.*, 2013).

These schemes rely on the hypothesis that technical bias affects uniformly all genes in a given sample. Therefore, non-differentially expressed genes should have the same level of normalized counts between conditions, on average. A normalization factor can therefore be derived for each sample by equalizing read counts of nondifferentially expressed genes to a reference sample or a pseudoreference. In the TMM procedure, the reference sample is the first replicate of the first condition, whereas in the RLE and MRN procedures, a pseudoreference sample is defined as the geometric mean of all samples and the simple mean of the replicate of a given condition respectively.

For each sample, computation of the relative size of transcriptome with respect to the (pseudo) reference sample is based on gene-wise count ratio. As the bias is assumed to affect identically all genes, the same normalization factor can therefore be used for all genes within a given sample.

These normalization schemes are widely used and give roughly similar results (for a detailed description and comparison of these procedures see Maza (2016)).

It remains possible nevertheless that assumptions on which these normalization schemes rely are not verified in practice. This is especially true if all or most of the genes are overexpressed in one condition only (Athanasiadou *et al.*, 2016; Zheng *et al.*, 2014; Lin *et al.*, 2012; Zuqin *et al.*, 2012). In this special case, negative controls are needed. The negative control can be a gene for which relative expression between experimental conditions is known or a spike-in control. In the resulting normalizing procedure, scaling factors will be determined such that relative expression of the control gene (or spike-in control) matches its expected value between experimental conditions.

Of note, from (6), it appears that the expected fold change of read counts for a given feature between two conditions does not depend on length of that feature. Therefore, normalization within sample is not needed when differential expression is computed between samples (Soneson and Delorenzi, 2013; Oshlack *et al.*, 2010). Moreover, in this situation, any approximation resulting from a within-sample normalization procedure is likely to introduce bias in further differential expression

analysis, therefore within-sample normalization is not recommended when between-sample differential expression analysis is pursued (Dillies *et al.*, 2013).

Differential Expression From RNA-seq

At this stage, we assume an RNA-seq experiment where read counts of N genes were derived from biological samples from two conditions, say n_1 wild type samples and n_2 muted samples, which is arguably the most encountered experimental design for differential expression experiments (Soneson and Delorenzi, 2013). We assume also that a procedure such as TMM, RLE, or MRN has been used for read count normalization. Recall that the use of these normalization procedures relies on the assumption that most genes are not differentially expressed, the remaining genes being overexpressed and underexpressed in a balanced proportion (Dillies *et al.*, 2013; Bolstad *et al.*, 2003; Calza and Pawitan, 2010). Finally and despite an appropriate experimental design (Auer and Doerge, 2010), principal component analysis may reveal presence of batch effects, which can be removed using methods such as COMBAT (Johnson *et al.*, 2007) or ARSyN (Nueda *et al.*, 2012).

Discrete distribution of read counts

An RNA-seq experiment can be considered as a sampling procedure in which the probability of drawing a read mapping gene i is equal to the proportion of cDNA fragments arising from that gene. Under this sampling design, Y_i , the number of reads mapping gene i follows a binomial distribution with parameters N , the total number of reads for that sample and p_i , the unknown proportion of cDNA fragment arising from gene i :

$$Y_i \sim B(N, p_i) \quad (7)$$

As N far exceeds Y_i , the binomial distribution can be approximated by a Poisson distribution with parameter Np_i . This approximation is supported empirically in RNA-seq experiments even with technical replicates (Marioni *et al.*, 2008). In such experiments, as technical replicates can be seen as drawn from the same large pool of cDNA fragments, the resulting sum of counts for gene i will also follow a Poisson distribution with expected mean $p_i(N_1 + \dots + N_k)$ for k technical replicates.

On the other hand, in presence of biological replicates, counts mapping to a given gene are *overdispersed* as compared to counts arising from technical replicates for the same gene. In this situation, the Poisson approximation still holds for individual samples with expected counts for gene i in sample j being:

$$E[Y_{ij}] = N_j p_{ij} \quad (8)$$

However, in a given experimental condition the sampling design becomes a two-step scheme:

1. draw the parameter of the Poisson distribution for gene i and sample j from a distribution with support on the nonnegative real numbers, and
2. draw the count of reads for gene i in sample j (Y_{ij}) from a Poisson distribution with parameter obtained in 1.

That is, the parameter of the Poisson distribution is also a random parameter and the resulting distribution is a compound or a mixture of Poisson distributions. In practice the gamma distribution satisfies properties required for the parameter of the Poisson distribution (Anders and Huber, 2010; Robinson and Smyth, 2007a). The Poisson–gamma mixture distribution is commonly referred to as the negative binomial (NB) distribution with parameters μ and ν ($NB(\mu, \nu)$), with mean and variance:

$$E(Y) = \mu, \text{ and } \text{Var}(Y) = (\mu + \nu)\mu^2 \quad (9)$$

Other possible discrete distributions for modeling counts in RNA-seq experiments are the Poisson log-normal distribution (Bulmer, 1974; Lu *et al.*, 2005) or the quasi-Poisson distribution (Lund *et al.*, 2012).

Counts from a Poisson log-normal distribution are supposed to be drawn from a Poisson distribution with parameter e^z , Z being drawn from the normal distribution with parameters μ and σ^2 . The NB and Poisson log-normal distributions look similar for low values of μ and σ but diverge for larger values of σ , the NB distribution giving more weight to $P(y_{ij}=0)$, whereas the Poisson log-normal distribution puts more weight on its right tail (Love, 2013). Like the NB distribution, the quasi-Poisson distribution has two parameters. However, the variance of the quasi-Poisson distribution is a linear function of its mean, whereas in the NB distribution the variance is a quadratic function of the mean. The choice of an appropriate distribution can therefore be based on the variance-to-mean relationship (Ver Hoef and Boveng, 2007). As RNA-seq experiments involves few replicates, the diagnostic plot may include all read counts of an experiment.

Once a distribution is chosen, the hypothesis of equal mean in read counts between the two conditions can be tested using the generalized linear model (GLM) framework. Using the NB distribution, we have:

$$Y_{ij} \sim NB(\mu_{ij}, (\nu)_i) \quad (10)$$

and

$$\log_2(\mu_{ij}) = x_j^t \beta_i \quad (11)$$

where μ_{ij} is the mean parameter of the NB distribution, that is the expected value of read count for gene i in sample j , ν_i is the overdispersion parameter for gene i , x_j is a column vector of covariates for sample j , and β_i a column vector of coefficients associated to gene i . The link function here is the $\log_2$ function for interpretation convenience. In a simple RNA-seq experiment

with two conditions, β_i can be written as:

$$\beta_i = \begin{pmatrix} \beta_{i,0} \\ \beta_{i,1} \end{pmatrix} \quad (12)$$

In this formalism, $\beta_{i,0}$ represents the $\log_2$ of the mean of normalized counts in the first condition and $\beta_{i,1}$ represents $\log_2$ fold change between conditions 1 and 2. For instance, with $\beta_a^t = (10, 1)$, and sample 1 and 2 being in the first and the second condition respectively, we have:

$$x_1 = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \quad \text{and} \quad x_2 = \begin{pmatrix} 1 \\ 1 \end{pmatrix}$$

then for sample 1:

$$\begin{aligned} \log_2(\mu_{a,1}) &= x_1^t \beta_a = (1 \ 0) \begin{pmatrix} 10 \\ 1 \end{pmatrix} = 10 \\ \Rightarrow \mu_{a,1} &= 2^{10} = 1024 \end{aligned}$$

and for sample 2:

$$\begin{aligned} \log_2(\mu_{a,2}) &= x_2^t \beta_a = (1 \ 1) \begin{pmatrix} 10 \\ 1 \end{pmatrix} = 11 \\ \Rightarrow \mu_{a,2} &= 2^{11} = 2048 \end{aligned}$$

Then, the hypothesis of nondifferential expression between both conditions (H_0) can be tested with the Wald test. Using the standard iteratively reweighted least squares (IRLS), the maximum likelihood estimate is derived for $\beta_{a,1}$ as well as its standard deviation ($\text{se}(\hat{\beta}_{a,1})$). Under H_0 , $\hat{\beta}_{a,1}/\text{se}(\hat{\beta}_{a,1})$ follows approximately a standard normal distribution. If $|\hat{\beta}_{a,1}|/\text{se}(\hat{\beta}_{a,1}) > U_{1-\alpha/2}$, where α is a prespecified type I error rate, gene a is called differentially expressed between conditions 1 and 2.

Borrowing strength across genes

From a practical point of view however, as RNA-seq experiments involve often small number of biological replicates, estimation of both parameters of the NB model remain challenging. Especially, a poor estimation of the overdispersion parameter can lead to unreliable estimates of the standard error of the mean parameter and therefore leads to false positive or false negative calls. To overcome this difficulty and take advantage of the massively parallel structure of the data, various methods were developed. [Robinson and Smyth \(2007\)](#) proposed to reduce ([Robinson and Smyth, 2007b](#)) or shrink ([Robinson and Smyth, 2007a](#); [Wu et al., 2013](#)) the gene-wise estimate of ν to a common value estimated from the whole dataset. [Love et al. \(2014\)](#) moderate the gene-wise dispersions by assuming a log normal prior on this parameter conditional on mean counts for a given gene. These approaches are implemented in the edgeR ([Robinson et al., 2010](#)) and the DESeq2 ([Love et al., 2014](#)) R libraries respectively.

Parametric approach on transformed counts

It has been argued that after extensive normalization and/or batch effect removal the read counts data have eventually lost their discrete nature, allowing practitioners to use parametric model and statistical workflows developed for microarray data. This approach has been used since the emergence of RNA-seq experiments after appropriate counts transformation ([Law et al., 2014](#)). However, the main challenge here is to transform RNA-seq data in order to meet hypotheses allowing the use of parametric linear regression models also used for microarray data, assumed to follow log-linear distributions.

In the linear regression model framework, the response variable k is assumed to be a linear combination of the predictors X plus an error term and the hypothesis of homoscedasticity implies that the error term is independent of X and k . However, one of the characteristics that have led to the use of Poisson distributions or compound Poisson distributions for modeling RNA-seq data is heterogeneous dispersion, i.e., heteroscedasticity. When a linear mean-variance relationship is suspected (relation (9)), the square root transformation of counts can stabilize the variance of mean counts ([t Hoen et al., 2008](#)), but more sophisticated procedures such as variance stabilizing transformations developed for microarray data ([Huber et al., 2002](#); [Durbin et al., 2002](#)), or the $\log_2$ transformation can be used if counts are overdispersed ([Zwiener et al., 2014](#)).

It has been shown nevertheless that variance stabilizing transformations such as the log-transformation would result in a reduced variance for large counts as compared to small counts ([Law et al., 2014](#)). To overcome this difficulty two approaches developed to stabilize variance of RNA-seq count data have been proposed. In the first approach denoted as *vst* (variance stabilizing transformations), the moderate gene-wise dispersions of a NB model ([Love et al., 2014](#)) are used as a variance stabilizing parameter ([Anders and Huber, 2010](#)). In the second approach, denoted as the *voom* method (variance modeling at the observation-level), a mean-variance trend is estimated nonparametrically ([Cleveland, 1979](#)) from the dataset of normalized log-counts. Fitted values associated to each individual normalized log-count are then incorporated into *precision weights*, which are used in the downstream statistical inference step of dedicated statistical pipelines such as the *limma* suite ([Smyth, 2004](#); [Ritchie](#)

et al., 2015). Of note it has been reported that this approach performs well as compared to methods based on discrete distribution of read counts (Soneson and Delorenzi, 2013; Law *et al.*, 2014).

Conclusion

Since the 1990s, progresses in genetic engineering and information technologies have allowed the sequencing of the human genome (Human Genome Sequencing Consortium International, 2004) as well as many other model organisms. At the same time, these advances have provided prior knowledge needed to perform gene expression profiling experiments using cDNA and oligonucleotide microarrays (Schena *et al.*, 1995; Lockhart *et al.*, 1996; Brown and Botstein, 1999). Since the pioneering work of Schena *et al.* (1995) tens of thousands of scientific publications have referred to gene profiling experiments using microarrays (Fig. 2). More than a decade later, and owing for the advent of high-throughput sequencing platforms, the sequencing-base approach or RNA-seq has emerged as a promising tool for gene expression profiling, as it allows both the mapping and the quantification of the sum of transcripts extracted from a biological sample. RNA-seq presents many advantages over array-based approaches, such as an higher sensitivity and dynamic range as well as a lower background noise (Wang *et al.*, 2009; Griffith *et al.*, 2010; 't Hoen *et al.*, 2008). This approach benefits also from the decrease of sequencing costs and is now the most widespread method used in gene profiling experiments (Fig. 2).

Results of gene profiling experiments using high-throughput technologies such as microarrays or RNA-seq consist of large numerical matrices in which expression level of many genes are recorded from few biological samples. Intensity records from microarrays are assumed to follow a log-normal distribution, whereas RNA-seq experiments produce counts assumed to follow Poisson related distributions. Though nonparametric approaches have also been proposed such as in Li and Tibshirani (2013) or Tarazona *et al.* (2011) most of the methods used in practice assume probabilistic distributions to expression values in order to fit parametric models in the framework of linear models or GLM theory (McCullagh and Nelder, 1989). Despite allowances that have to be made for a specific distributional hypothesis, and the choice of a model, the analysis of large scale expression data remains a high-dimensional inference problem.

In this context, empirical Bayes methods (Efron and Morris, 1973; Efron and Morris, 1977; Carlin and Louis, 1996) have provided a general theoretical framework to analyze large scale gene expression data (Newton *et al.*, 2001; Smyth, 2004; Lönnstedt and Speed, 2002; Baldi and Long, 2001; Robinson *et al.*, 2010; Anders and Huber, 2010; Love *et al.*, 2014; Robinson and Smyth, 2007a; Hardcastle and Kelly, 2010; Leng *et al.*, 2013; Van De Wiel *et al.*, 2013; Yanming *et al.*, 2011). The key point of empirical Bayes methods, and related methods, states that optimal statistical procedures to infer from a single feature became suboptimal for high-dimensional inference problems (Stein Charles, 1955). This result implies that more efficient procedures involving sharing information across features exist. In practice, estimation of a given statistic, say the standard deviation of the expression of a gene through biological samples, is shrunk toward a common value, or distribution, estimated from other genes. This principle has been applied to microarray data to moderate the denominator of test statistics and therefore prevent erratic values of the test statistic observed by chance. By preventing false positive and false negative calls, these procedures result in more stable inferences and provide therefore overall higher statistical power.

This principle has been also acknowledged for RNA-seq statistical procedures in which estimation of the dispersion parameter for each gene remains crucial while small sample size is generally involved. This situation has therefore motivated the development of empirical Bayes approaches involving information sharing across genes to obtain more reliable estimates of single dispersion parameters and improved overall inference procedure. Empirical Bayes approaches are also *de facto* convened when RNA-seq read counts are transformed using variance stabilizing procedures to enter subsequent microarray analysis pipelines.

Many tools exist to compute differential expression, none of which perform optimally in all circumstances (Soneson and Delorenzi, 2013; Conesa *et al.*, 2016). The practitioner challenge remains therefore to design a strategy that suits its particular needs, possibly in view of performances of the different tools as reported in similar experimental conditions, for instance in terms of their sensitivity/specificity and control of the FDR (Conesa *et al.*, 2016). Of note, analysis requirements such as the need to adjust results for confounding covariates and to perform multiple comparisons may also limit the list of available options to software allowing for complex statistical designs, generally in the theoretical background of GLMs and empirical Bayes procedures such as limma (Smyth, 2004) svt/voom-limma (Smyth, 2004; Law *et al.*, 2014; Love *et al.*, 2014), edgeR (Robinson *et al.*, 2010), or DESeq (Love *et al.*, 2014). The choice of an analysis strategy may also depend on individual preferences and habits, the quality of the documentation of software, and the existence of an active community of users.

Introduction

Quantification of gene expression is very important in biological and biomedical research. A major breakthrough in gene expression analysis is the development of DNA microarrays in the 1990s (DeRisi *et al.*, 1997; Schena *et al.*, 1995). Prior to the development of DNA microarrays, expression of genes is mainly measured by relatively low-throughput experimental techniques such as quantitative polymerase chain reaction (qPCR), Southern and Northern blotting. All these techniques measure the absolute or relative amount of a small number of target complementary DNA (cDNA) or RNA molecules in a sample. One key innovation of microarray technology is its ability to simultaneously measure the expression of thousands of genes in a single assay. It enables researchers to ask new questions about the entire gene expression system as a whole, instead of focusing on individual molecules one at a time.

In late 2000s, the advent of next-generation sequencing (NGS) brought about the next major breakthrough in gene expression analysis, namely RNA sequencing (RNA-seq) (Cloonan *et al.*, 2008; Mortazavi *et al.*, 2008; Nagalakshmi *et al.*, 2008; Wilhelm *et al.*, 2008). The idea is very simple. Expressed RNA transcripts are reversed transcribed into cDNA, which can be amplified, fragmented, and sequenced using NGS technologies. Expression of a gene can be quantified by the number of sequence reads aligned to the reference transcriptome. The raw readout of RNA-seq is therefore read counts of each gene, which can then be further normalised by the total number of reads in a library and sometimes by gene length. RNA-seq is found to have better detection sensitivity and specificity than microarrays (Bottomly *et al.*, 2011; Fu *et al.*, 2009; Marioni *et al.*, 2008). It is also much more flexible since we are no longer restricted by the collection of probes that are available on a microarray. RNA-seq is currently the preferred method for gene expression profiling (Wang *et al.*, 2009).

Regardless of the technology used to obtain the gene expression profiles, the aim of gene expression profiling is to identify similarities and differences in gene expression patterns among a group of samples from different biological conditions (i.e., phenotypic, genotypic, temporal, or environmental differences). Each sample can be derived from a cell line or tissue from an individual or an experimental animal model. A microarray data set is commonly represented by an $n \times m$ matrix,

$$\begin{bmatrix} x_{1,1} & x_{1,2} & \cdots & x_{1,m} \\ x_{2,1} & x_{2,2} & \cdots & x_{2,m} \\ \cdots & \cdots & \ddots & \vdots \\ x_{n,1} & x_{n,2} & \cdots & x_{n,m} \end{bmatrix}$$

where n is the number of genes and m is the number of samples. Each element $x_{i,j}$ in the matrix represents the expression value of gene i and sample j . For example, in a study that profiles the genome-wide mRNA expression levels of 50 heart disease patients and 50 matched healthy individuals, n is approximately 20,000 (the number of protein coding genes in human), and m is 100. Gene expression analysis refers to the manipulation of this matrix.

The use of genome-wide gene expression profiling in biological or biomedical research has grown rapidly in the last decade. One of the most widely used public repositories of gene expression data is the National Centre for Biotechnology Information (NCBI) Gene Expression Omnibus (GEO) (Barrett *et al.*, 2005, 2013). To date (October 2017), GEO contains gene expression profiles from close to 2 million samples. These gene expression profiles cover many species, cell types, and biological conditions. Proper analysis of these data is crucial in bioinformatics.

One of the most basic analyses that one can perform on a gene expression matrix is clustering (Eisen *et al.*, 1998). This includes the clustering of genes and clustering of samples. Roughly speaking, the goal of clustering is to group objects into clusters such that similar objects are grouped in a cluster, whereas dissimilar objects are grouped in different clusters. In the context of gene expression analysis, clustering can be performed to cluster genes (where each gene is represented by its expression across a number of samples) or samples (where each sample is represented by the expression of the genes).

A small data set is shown in Fig. 1 to illustrate the power of gene expression clustering. This toy data set consists of 10 genes and 8 samples. A popular way to visualise a gene expression matrix is to use a heat map. In the heat map in Fig. 1, red indicates high gene expression and blue indicates low expression. Without clustering, it is quite difficult to discern any patterns in this gene expression matrix. After clustering is performed on the genes and samples (hierarchical clustering is used in this case), we could reorder the genes and samples such that genes/samples that are within the same cluster are closer together. Clear patterns emerge from the clustering analysis. We can readily identify three groups of samples: the brown cluster (sample 2, 6, and 7), blue cluster (sample 1 and 3), and the red cluster (sample 4, 5, and 8). We could also identify three distinct groups of genes: the green cluster (gene 6, 7, and 10), the yellow cluster (gene 4 and 9), and the purple cluster (gene 2, 3, and 8). There are also 2 genes that have expression patterns that are quite distinct from other gene clusters. They can be viewed as outliers.

Fig. 1 A toy example illustrating the power of gene expression clustering in discovering groupings of samples and genes. A gene expression matrix consists of 10 genes (rows) and 8 samples (columns) are subjected to clustering analysis. After hierarchical clustering, it is much easier to identify three distinct groups of samples, and three sets of co-expressed genes, along with two 'outlier' genes that have very distinct expression patterns compared to other gene clusters.

Michael Eisen and colleagues were one of the first groups that applied clustering to analyse and visualise gene expression data (Eisen *et al.*, 1998). Through clustering of genes, they were able to show that genes of similar functions tend to group together in a cluster. This is a major observation because it suggests that genes that have similar expression patterns across multiple samples may be co-regulated at the cellular level. This motivated the use of clustering to identify co-expression modules as a way to discover cellular gene regulation programs (Basso *et al.*, 2005; Friedman *et al.*, 2000; Stuart *et al.*, 2003). Furthermore, clustering of samples can lead to discovery of patient subtypes and rare cell types (Golub *et al.*, 1999; Ramaswamy *et al.*, 2001; Su *et al.*, 2001). Nowadays, clustering is one of the most routinely performed analyses on gene expression data.

Clustering Methods

Clustering is an unsupervised method to discover patterns in the data. It is unsupervised because it depends on the data alone (i.e., gene expression values only), without the need to include additional information about how the data should be grouped. Clustering can be framed as an optimisation problem in which the objective is to maximize the similarity between every item within each subset (i.e., cluster), and maximize the dissimilarity between every subset (i.e., cluster). Solving this optimisation problem exactly is computationally difficult because in general one needs to enumerate all k^n possible clustering configurations to identify the optimal clustering for n points and k clusters. Instead, various algorithms have been developed to find a good local optimal solution (Jain *et al.*, 1999). In this section, we will review three of the most popular clustering methods used in gene expression analysis: k -means clustering, hierarchical clustering, and DBSCAN (Fig. 2). All these methods are easily accessible via the scikit-learn package in python (Pedregosa *et al.*, 2011) and the cluster (Maechler *et al.*, 2017) and dbscan (Hahsler *et al.*, 2017) packages in R.

K-Means Clustering

K -means clustering is a partitional clustering method, in which a set of items is partitioned into k disjoint subsets such that each item belongs to exactly one subset. The basic idea of k -means is that each cluster is assigned a cluster centre (i.e., cluster mean), and the optimisation objective is to minimise the distance between each data point and its closest cluster centre. The classical k -means clustering algorithm starts with selecting k random data points as the initial cluster centres, and iteratively perform the following two steps:

- 1) Assigns each point to its closest cluster centre
- 2) Based on the points in each cluster after step 1, calculate the cluster mean and make it the new cluster centre

Fig. 2 Illustration of three popular clustering methods: (a) *k*-means clustering, (b) hierarchical clustering, and (c) DBSCAN.

These two steps are repeated until the maximum number of iteration is reached or the cluster assignment no longer change (i.e., no points are re-assigned in step 1). The *k*-means algorithm is fast and simple. The algorithm works very well for ball-shape and cubic-shape clusters, especially when *k* (the number of cluster) is somehow known. *K*-means is memory efficient, and it is easy to parallelise (Zhang *et al.*, 2011). Nonetheless, *k*-means is sensitive to the initialisation of cluster centres. To improve the quality of clustering, *k*-means++ has been developed (Arthur and Vassilvitskii, 2007). The idea is to perform a simple randomised seeding step to obtain good initial cluster centres. This simple step has been shown to significantly improve both clustering accuracy and speed (by reducing the number of iterations required).

Hierarchical Clustering

The key difference between hierarchical clustering and *k*-means clustering is the structure of clusters. While *k*-means clustering groups all points into distinct non-overlapping clusters, hierarchical clustering groups all the points in a tree-like hierarchy, also known as a dendrogram. The root of the tree represent the whole data set and every branch node represents a subset of the data. Hierarchical clustering methods are categorised into agglomerative (bottom-up) and divisive (top-down) algorithms. In bioinformatics, the agglomerative algorithm is more popular, and therefore will be the focus of this section.

The basic idea of agglomerative hierarchical clustering is recursive agglomeration of two nearest clusters or data points. Agglomeration criteria include single-linkage, complete-linkage, averaged-linkage clustering, and the Ward's method. Different linkage criteria can lead to different results, with the Ward's method generally considered to produce consistently good results for expression data (Meunier *et al.*, 2007). The Ward method (Ward, 1963) merges two clusters with minimum weighted squared distance between the new cluster centres.

In the initial step of the agglomerative hierarchical clustering algorithm, each of the *n* points is labelled as a distinct cluster. Then an *n*×*n* dissimilarity matrix is calculated to reflect the dissimilarity (or distance) between every pair of clusters. Clusters are then recursively merged to form larger clusters based on the following steps:

- 1) Merge two clusters with minimum cluster distance (based on the an agglomeration criterion)
- 2) Update the dissimilarity matrix

The two steps are repeated until only one cluster is left.

The main benefit of hierarchical clustering is that there is no need to determine the number of clusters prior to the analysis. This allows information about the relationships between different clusters (or data points) to be preserved. If it is desirable to obtain discrete clusters, one can always 'cut' the dendrogram at a certain level to obtain them. In practice, one drawback of hierarchical clustering is that the pairwise dissimilarity matrix can become prohibitively large when the number of data point is large, which makes clustering impractical for data sets with more than several thousand points using standard computers.

DBSCAN

Density based clustering (Kriegel *et al.*, 2011) is a category of algorithm that could detect clusters of any shape by dividing a data set into a set of connected 'high density' components. It includes DBSCAN (Ester *et al.*, 1996), OPTICS (Ankerst *et al.*, 1999) and DENCLUE (Hinneburg and Keim, 1998). The key idea is to define a cluster as a region in the data space that has high density, separated from other clusters by low density regions. The definition is intuitive, does not require the number of clusters to be predetermined, and has the potential to recover complex non-spherical clusters. DBSCAN is a frequently used density-based clustering method in bioinformatics. The basic idea of DBSCAN is outlined as follows (Schubert *et al.*, 2017):

- 1) Go through every point in the data set to check if each point *p* has at least *m* neighbours within a distance of ϵ . If *p* satisfies this criterion, it is said to be a core point. Otherwise, it is a non-core point.

- 2) Join neighbouring core points into clusters
- 3) Go through each non-core point, and try to joint it to a reachable cluster. If this point can be joint, it becomes part of that cluster. Otherwise this point is said to be an outlier (or noise).

With suitable user-specified parameters (m and ε), DBSCAN can work very well in detecting clusters with complex shape, and in the presence of outliers. DBSCAN is fast and has low memory requirement. However, its performance is sensitive to the choice of parameters and data dimensionality. A large ε may merge too many clusters into one, while a small ε may incorrectly create too many outliers. In high dimension, finding suitable parameters becomes very difficult because of the increased sparsity. Various improvements have been made to the original DBSCAN algorithm (Rehman *et al.*, 2014). For example, FDBSCAN dramatically reduces the query time of neighbours and the effect of user-specified parameters (Liu, 2006).

Evaluation and Interpretation of Clustering Results

Of the three clustering algorithms discussed in the previous sections, k -means algorithm generally scales very well with increasing number of data points because its algorithmic complexity is linear with respect to the number of data points. K -means is especially helpful if the user has prior knowledge about the expected number of clusters. Nonetheless, k -means clustering is ineffective in discovery clusters that have a non-spherical shape. Also, the results are highly sensitive to the presence of outliers (Gan and Ng, 2017). Therefore, it is important to visualise and carefully inspect the quality of the resulting clusters to ensure they are not subjected to significant biases.

Hierarchical clustering provides more information than flat partitional clustering. It is particularly useful in the case where we have no idea what the correct number of cluster should be. Nonetheless, the algorithm requires quadratic runtime and space. This means in practice it is often not possible to cluster more than several thousand points on a standard desktop machine. If the number of points is small, hierarchical clustering can often provide a highly informative view of the clustering structure of the data.

Density-based clustering algorithms such as DBSCAN is much more flexible in terms of detecting complex cluster structures, and they can deal with larger data sets as these algorithms generally scale quasi-linearly with the number of points. One major drawback with DBSCAN is that the determination of local density is very sensitive to increased dimensionality. Also, choosing the right parameters can often be quite difficult.

It should be noted that most clustering methods find clusters even when there is no natural clustering structure in the data. Therefore it is important to evaluate the quality of the clustering results and interpret its significance cautiously (Altman and Krzywinski, 2017; Ronan *et al.*, 2016). Data preprocessing and dimensionality reduction can dramatically affect the quality of clustering results (see discussion in the following section).

In terms of evaluation of the quality of the clustering results, if there is external information (such as sample labels or even partial labels), such information can be used to determine whether a clustering is reasonable or not. For example, if all the labels are given, one can calculate an adjusted rand index to quantify the accuracy of the clustering. Often only partial information is given, such as which samples are replicates. In this case, one might consider the quality of the overall clustering based on whether replicates are correctly grouped together.

Practical Considerations

In gene expression analysis, one of the most important decisions is to identify the appropriate feature set. A genome-wide gene expression data set typically contains the expression levels of tens of thousands of genes. Prior to clustering, it is often useful to perform dimensionality reduction to reduce the number of features used in the clustering analysis. This may be necessary because of both biological reasons and technical reasons.

In terms of biological reasons, sometimes scientists want to focus on a specific set of key genes, such as transcription factors, receptors, or signalling molecules. In this case, it is useful to only include these key genes in clustering analysis to discover clusters based on these key genes.

If there is no prior knowledge about which genes should be included in the analysis, there are still a number of technical reasons why dimensionality reduction is necessary in practice. In microarray data analysis, often a gene is represented by several probes. One might wish to first combine the expression levels of multiple probes to generate a single expression value for each gene. Several methods are possible, such as only including the probe with the highest median expression level, or simply taking the average of the probe expression values.

Furthermore, it is often observed that many genes have no detectable expression across all the samples profiled in the entire data set. In this case, including those non-expressed genes in the clustering might artificially inflate the dimensionality of the data without providing any real signal for clustering. It is often advisable to remove these 'undetectable' genes, using criteria such as removing all genes which have detectable expression in less than 2 samples.

After all these filtering steps, a genome-wide gene expression data set may still have a large number of genes (i.e., in the order of thousands). Clustering high dimensional data can often be problematic, because as the number of dimensions increases, the space become more sparse, and the difference between within- and between-cluster distances become smaller – this phenomena is known as the curse of dimensionality. Many methods have been designed to deal with clustering of high dimensional data (Assent, 2012), but as a general rule, doing sensible feature selection and dimensionality reduction is often critical in gene expression analysis.

A simple method for feature selection involves only selecting features that have the high variance (or some measure of variability) across all the samples in the data set. For example, one might consider selecting only those genes in which the maximum and minimum expression levels are at least 2 fold different. Besides feature selection, another popular dimensionality reduction method is Principal Component Analysis (PCA) (Ma and Dai, 2011). PCA identifies a series of orthogonal principal components (PCs), in which each PC corresponds to a linear combination of the original features. The PCs are constructed such that the first PC (PC1) contains the largest proportion of variance of the data, followed by PC2, then by PC3, and so on. Dimensionality reduction can be achieved by selecting only the first k PCs that cumulatively explain sufficient proportion of variance. In other words, PCA is used to project a data set of n dimensions into k projected PCs.

Another important consideration in gene expression clustering analysis is the definition of distance between two points (two genes or two samples). In practice, the most common distance measures are Euclidean distance and Pearson correlation coefficient (when used as a distance, it is typically represented as $1 - |\text{correlation}|$ or $(1 + \text{correlation})/2$). A more comprehensive comparison of distance measures for gene expression clustering can be found elsewhere (Jaskowiak *et al.*, 2014).

Correlation coefficient is less sensitive to the scale of data than Euclidean distance. Consider the case of a pair of co-expressed genes in which one gene is highly expressed while other one has significantly lower expression. These two genes would have a large Euclidean distance but strong correlation. In this case the choice of Euclidean distance or correlation as a measure of dissimilarity is largely driven by the underlying biological question. Sometimes it might be important to distinguish genes that have large difference in expression levels, whereas sometimes it is more important to determine correlation without worrying too much about the absolute expression levels. Another possible analysis strategy is to first normalise the expression of both genes to have a mean of zero and a standard deviation of one (i.e., conversion to standardised scores). In this case, both Euclidean distance and correlation would yield similar results.

Euclidean distance and correlation coefficient are both sensitive to outliers or missing data. Missing data is a major issue in the analysis of single-cell RNA-seq (scRNA-seq) data because many transcripts are not detectable due to dropout events in the experimental process. In the case of scRNA-seq data, it is often not possible to distinguish whether a lack of gene expression (zero read count per gene) is an artefact caused by dropout or it reflects true non-expression of that gene. One simple approach to alleviate the impact of dropouts in scRNA-seq data set is to use ‘implicit imputation’ in the calculation of Euclidean distance (Lin *et al.*, 2017). This approach is implemented in an R package CIDR for dimensionality reduction and clustering of scRNA-seq data.

Case Study

Let’s put everything together. In this case study, we analysed a time series gene expression data set of mouse embryonic dental epithelium (Epi) and dental mesenchym (Mes) between embryonic day 11.5 and 13.5 (E11.5-E13.5) (O’Connell *et al.*, 2012), with three replicates per time point per tissue. This data set consists of 30 gene expression profiles in total (5 time points x 2 tissues x 3 replicates). The gene expression profiles were obtained by an Illumina microarray platform. The data can be downloaded from GEO using accession number GSE32321. The goal of the analysis is to identify the gene expression dynamics in these two adjacent developing dental tissues, and to identify genes that are driving those dynamic patterns.

After downloading the data, we first checked that the quality of the data. Fig. 3(a) shows the histogram of expression levels (in logarithmic scale) of one representative sample in the data set. This plot illustrates the characteristics of a microarray-based gene expression profile: a sharp peak on the left which consists of mostly unexpressed or lowly expressed genes, and a long tail on the right which consists of expressed genes. Based on this plot, approximately half of the genes are unexpressed or have low expression (the left peak), and the other half has a wide range of expression levels (the long right tail). The plot also shows that there is an absence of outliers (values that are exceptionally small or large). These are all characteristics of a good quality gene expression profile. In RNA-seq data, the distinction between the left peak and the right tail is often much clearer.

We next checked whether the gene expression distributions were consistent across all samples in a data set. Fig. 3(b) is a boxplot showing the distribution of all 30 samples in this data set. The interquartile range and median of all the samples are highly consistent, suggesting that further normalisation is not necessary.

We then wanted to visualise the gene expression data using a heat map. Nonetheless, rendering a heat map of the entire data set (consisting of 45,281 gene probes) is computationally difficult on standard computer screens and difficult to visually interpret by humans. We therefore decided to analyse and visualise the 100 most variably expressed genes, as defined as the 100 genes with the highest variance across the 30 samples. Analysis of these high-variance genes often allows us to gain insight into the major significant patterns in the full data set. We performed hierarchical clustering on the genes and samples. The hierarchical clustering was performed using Euclidean distance and the Ward method for aggregation. The results are displayed using a heat map in which a gene represent as a row and a sample is represented as a column (Fig. 3(c)). One striking feature is that samples from epithelial and mesenchymal tissues are grouped into two distinct clusters. The replicates generally group together, with only one minor exception (E11.5 epithelium), suggesting that the replicates are generally highly consistent. Within each tissue, the samples appear to be grouped based on temporal ordering of samples. In particular, samples from E11.5 and E12 tend to group together, and samples from E12.5-E13.5 tend to group together.

We further visualised the relationships among the samples by performing PCA, and displaying the sample based on the first two principal components (PC1 and PC2; Fig. 3(d)). The first two components collectively explains about 90% of the variance in the data set, with most of the variance explained by the PC1 (76%). We can see that PC1 clearly separates epithelial and mesenchymal tissues. PC2

Fig. 3 A case study on expression clustering of an embryonic dental tissue development data set. (a) The gene expression distribution of a typical sample in this data set. (b) A box plot showing the distribution of gene expression values is largely consistent across all the samples in the data set. (c) A heat map showing the gene expression levels of the 100 most variably expressed genes in this data set. Hierarchical clustering has been performed on the samples and genes. The clustering results are displayed as dendrograms around the heat map. (d) The data set is subjected to the principal component analysis (PCA), and the samples are displayed based on first two principal components (PC1 and PC2). (e) The top 100 variably expressed genes are subjected to k -means clustering to identify 6 clusters. The dark line in each plot represents the mean expression pattern of all the genes in a cluster.

generally separates early time points (E11.5 and E12) and later time points (E12.5-E13.5) in both tissues. This implies that there is a major transcriptomic change between E12 and E12.5 in both tissues. This plot clearly shows the spatial temporal clustering of samples.

Finally we would like to identify clusters of genes with similar gene expression patterns. Here we only analysed the epithelial samples for simplicity (the mesenchymal samples can be analysed in a similar manner). We first normalised the data such that each gene has a mean value of zero and a standard deviation of one. This process ensures that all the genes are comparable in scale. After normalisation, we performed k -means clustering to identify clusters of genes. In this example, we set $k=6$, but in general one should attempt a reasonable range of k . The resulting 6 clusters are displayed in Fig. 3(e). One salient pattern is that all clusters have a major transition point at E12.5, corroborating the pattern observed in the PCA plot (Fig. 3(d)). Through looking at the plots, some clusters can clearly be further divided into smaller clusters. For example, cluster 6 clearly consists of two major clusters – one characterised by a smooth and gradual increase in expression of mostly highly expressed genes, and the other characterised by a massive up-regulation of lowly expressed genes starting at E12. Further downstream bioinformatics analyses, such as gene set analysis (Djordjevic *et al.*, 2016; de Leeuw *et al.*, 2016), can be performed to identify what are genes that are enriched in each of these clusters.

This case study illustrates how clustering of genes and samples of a gene expression data set can lead to discovery of biologically relevant patterns, and highlight the overall workflow of clustering in gene expression bioinformatics analysis.

Summary

Clustering is one of the most fundamental bioinformatics tools, especially in terms of gene expression analysis. As discussed in this article, care must be taken to ensure that proper feature filtering, dimensionality reduction and quality controls are undertaken prior to clustering. Also, clustering results must be evaluated and interpreted carefully, especially mindful of the characteristics of different clustering algorithms. When performed properly, clustering is a powerful tool to discover co-regulated genes, patient groupings, and sub-population of cells.

Biographical Sketch

Xiaoxin Ye is a Masters student at the University of New South Wales (UNSW), and an intern at the Bioinformatics and Systems Medicine Laboratory at the Victor Chang Cardiac Research Institute. He received his BSc in Statistics from Guangzhou Medical University and a Graduate Certificate in Mathematics and Statistics from UNSW. His research focuses on developing fast and scalable algorithms for clustering single cell RNA-seq (scRNA-seq) data. His interests include scalable clustering algorithms, shared neighbours clustering algorithms, as well as statistical and parallelised machine learning.

Joshua Ho is the Head of Bioinformatics and Systems Medicine Laboratory at the Victor Chang Cardiac Research Institute in Sydney Australia. He is also a conjoint Senior Lecturer at UNSW Sydney. Dr Ho completed his BSc (Hon 1, Medal) and PhD in Bioinformatics at the University of Sydney, and undertook postdoctoral research at the Harvard Medical School in the United States. His current research focuses on developing fast and reliable bioinformatics methods to identify the genetic cause and mechanism of heart diseases, using a range of approaches such as whole genome sequencing, single-cell RNA-seq, ChIP-seq, machine learning, systems biology, cloud computing, and software testing and quality assurance. His research excellence has been recognised by the 2015 NSW Ministerial Award for Rising Star in Cardiovascular Research, the 2015 Australian Epigenetics Alliance' Illumina Early Career Research Award, and the 2016 Young Tall Poppy Science Award.

Metabolome Analysis

Introduction

Metabolites, including lipids, are biological active compounds important as building blocks for macromolecules and carriers of energy, both required in all living cells to participate in all biological processes. They are members of thousands of biosynthetic pathways providing the chemical diversity to fulfil specific functions. The chemical diversity of metabolites is enormous and has challenged biochemists and physiologists to provide knowledge on many biological processes.

This challenge has led to the development of metabolomics utilizing technological advances in analytical chemistry; it is today a scientific field used in many sectors, including biomedicine, plant and agricultural sciences, food and beverage sciences, microbial and environmental sciences, forensic, and many more. The analytical challenge is to tackle mostly the chemical diversity of metabolites which are characterized by thousands of unique chemical structures with diverse physical and chemical properties, including molecular weight, molecular size and shape, polarity, stability, volatility, solubility, and so on. These chemical and physical features determine the requirements for extraction, separation, detection and quantification. Therefore, a range of complementary methodologies for extraction and analysis must be used to cover the range of metabolites present in any living cell, making metabolomics an exciting playground for analytical chemists and biochemists.

A range of analytical instrumentation has been successfully utilized to analyze metabolites in many different organisms, tissue types or biofluids. These include Mass Spectrometry (MS) and Nuclear Magnetic Resonance (NMR) for the detection and quantification of metabolites, the former often coupled to chromatographic separation techniques to separate the highly complex metabolite extracts obtained from any biological sample. One of the well-established “work horses” in metabolomics is gas chromatography (GC) coupled to mass spectrometry. It is characterized by its great separation power and reproducibility, which allowed for the development of comprehensive mass spectral libraries for compound identification which are easily adaptable for routine applications on any GC–MS system available ([Hill and Roessner, 2013](#)). GC–MS in general enables the analysis of around 400 compounds in a single run depending on tissue type, including amino, organic and fatty acids, sugars, amines and sterols. Important to note here is that GC–MS also plays an important role in metabolic flux analysis using stable isotope labelling techniques. This is because of its great ability to detect isotopic patterns in each metabolite detected therefore allowing quantification of stable isotope enrichments which can then be refereed back to actual carbon or nitrogen flux within a pathway of interest. One major drawback of GC–MS is, however, that only compounds which are either volatile or can be made volatile using chemical derivatization are amenable for analysis, which are mainly low molecular weight compounds, therefore complementary techniques such as liquid chromatography (LC) coupled to MS need to be used to cover the diversity of the metabolome.

LC-MS in metabolomics has attracted enormous attention in the past few years, mainly driven by great technological step-changes making LC-MS much for reproducible, sensitive and easy to use ([Hill and Roessner, 2014](#)). Today, common LC-MS methodologies allow analysis of thousands of metabolites simultaneously, therefore covering a large portion of the metabolome, making LC-MS an ideal tool for biomarker discovery and for generating novel hypotheses. An important aspect for LC-MS-based metabolomics is the choice of separation chemistry and suitable elution procedures addressing the chemical diversity of the metabolome. Unfortunately, no single methodology is able to separate all compound classes found in any biological system. The main used separation chemistries are based on reverse phase and hydrophilic interactions, when considering different ionization techniques available, e.g. electrospray ionization or atmospheric pressure ionization, which will again ionize different compounds, and positive and negative ionization to cover differentially charged ions produced in the ionization process, the number of potential methods increase enormously. However, if one aims to measure “all” metabolites within a sample, all these different options need to be explored and utilized. Each individual approach may detect between 500 and 2000 compounds (depending on tissue type and extraction procedure), represented as mass features with an accurate mass, isotopic pattern and chromatographic retention time. Accurate mass and isotopic pattern in addition to secondary and tertiary MS-based fragmentation (MS^2 or MS^3) can aid structural elucidation of compounds. A difficulty in this approach are identifications of metabolites which are similar in structure, mass and their fragmentation patterns, such as sugars. This makes unambiguous identification almost impossible and therefore requires good chromatographic separation and confirmation of identification with authentic standards. Commercial and open source mass spectral libraries such as MassBank (see Relevant Websites section), Human Metabolome Database (HMD; see Relevant Websites section), Metlin (see Relevant Websites section) or ChempSpider (see Relevant Websites section) can aid identification, however often these libraries only record accurate mass of compounds but not their structure-specific fragmentation patterns or chromatographic retention times. Therefore unambiguous identification of compounds detected using LC-MS approaches remain limited leading to limited ability of biochemical and biological interpretation ([Sumner et al., 2014](#)). There have been many initiatives globally attempting to develop better solutions for metabolite identification such as [Creek et al. \(2014\)](#), [Bingol et al. \(2016\)](#), [Lynn et al. \(2015\)](#), [Pahler and Brink \(2013\)](#), [Shen et al. \(2014\)](#).

As described above, methodologies in metabolomics are as diverse as metabolites themselves, but taken together allow detection and quantification of thousands of compounds in any given sample. This leads to the almost greater challenge of extracting information from the analytical instrumentation, handling complex and multi-dimensional data sets and ultimately interpreting the vast amount of information in a biological context. This offers an exciting opportunity for collaboration between biologists, analytical chemists, bioinformaticians and statisticians to develop and apply sophisticated computational and statistical tools for metabolomics data analysis and interpretation. Below, we discuss in detail the various software and statistical tools and methods that are used for the analysis, visualization and interpretation of metabolomics data including metabolomics workflows, metadata, standards in metabolomics, data processing and workflow softwares, metabolomics experiments repositories, metabolomics databases and statistical analysis methods for analyzing metabolomics data. A collation of these software tools, repositories and databases are shown in [Table 1](#).

Metabolomics Workflow and Lims Solutions

The typical workflow of a metabolomics experiment starts with establishing the experimental design followed by sample collection, sample preparation, running of samples in analytical instruments, data processing, statistical analysis and pathway analysis ([Fig. 1](#)).

Of these steps, the first step of establishing the experimental design could easily be termed as one of the most important steps in the experimental workflow. Experiments that are setup with careful consideration of how different variables may affect the experimental outcome would produce the best results. Some of the basic aspects that needs careful consideration are establishing the correct groups, sampling the population appropriately such that the samples best describe the underlying population, establishing the number of sample (biological replicates) and reducing variability of samples within groups. The adage used so frequently in Computer Science ‘Garbage In, Garbage Out’ is well-suited for experimental designs and the eventual results they would produce. In order to establish the most suited experimental design that would best tease out the answer to the scientific query, consulting with a biostatistician before the beginning of the experiment is imperative. RA Fisher, the father of modern statistics and experimental design rightly said, “To call in the statistician after the experiment is done may be no more than asking him to perform a post-mortem examination: he may be able to say what the experiment died of.” (“RA Fisher” 1938). Therefore, statistical considerations of metabolomics experiments should not come into play after the data has been processed, but even before the experiment is designed.

Bioinformatics analyses of metabolomics data starts once the samples are run in analytical instruments and raw data generated. There are various algorithms and softwares that process the instrument generated raw data thereby converting them into a two-dimensional data matrix consisting of a measure of the different metabolites found in the samples. A detailed discussion of the data processing softwares of different platforms is presented below. After the raw data is processed and the data matrix obtained, various types of statistical analyses are performed in order to find metabolites that are significantly different between the compared groups. A detailed discussion on the different types of statistical tests is presented below. More often than not, statistical significance is determined using the p-value. In recent years, there have been substantial discussion in the scientific community about the dangers of relying only on measures such as the p-value to draw conclusions on the importance of a measured variable ([Baker, 2016](#); [Huber, 2016](#)). While p-values give a measure of statistical significance of the measured metabolites, this may not necessarily translate to biological significance. Other measures such as the 95% confidence intervals needs to be taken into consideration before deciding on the biological significance of metabolites. In metabolomics experiments, hundreds if not thousands of metabolites are measured and while investigating the significance of these metabolites, care must be taken to correct for multiple tests. When multiple tests of significance are performed as part of a single experiment, the resulting statistical significance needs to be controlled for false positives ([Curran-Everett, 2000](#)).

There are several softwares and software systems that focus on different parts of the metabolomics experimental workflow. Software systems known as Laboratory Information Management Systems (LIMS) focus on capturing all meta data and any resulting data of an experiment. Generally, LIMS solutions capture information about the project, the several experiments under the project, information on the type of analytical platforms the experiments are run, details of the runs themselves such as the analytical methods and any SOPs used and detailed information about the samples that are run. This include details such as the biological nature of the samples and any metadata associated with the samples such as age, sex, treatment, quantity, weight etc. There are several LIMS solutions currently present for metabolomics.

MASTR-MS ([Hunter et al., 2017](#)) is a web-based LIMS solution that can be deployed either within a single laboratory or in a collaborative multi-site network. It comprises a Node Management System that can be used to link and manage projects across one or multiple collaborating laboratories; a User Management System which defines different user groups and privileges of users; a Quote Management System where client quotes are managed; a Project Management System in which metadata is stored and all aspects of project management, including experimental setup, sample tracking and instrument analysis, are defined, and a Data Management System that allows the automatic capture and storage of raw and processed data from the analytical instruments to the LIMS. SetupX ([Scholz and Fiehn, 2007](#)) is a web based metabolomics LIMS solution that is XML compatible and built around a relational database management core. It is particularly oriented towards the capture and display of GC–MS metabolomics data through its metabolic annotation database, BinBase ([Skogerson et al., 2011](#)). SetupX is able to handle a wide variety of BioSources (spatial, historical, environmental and genotypic descriptions of biological objects undergoing metabolomic investigations) and

Treatments (experimental alterations that influence the metabolic states of BioSources). Sesame ("[Sesame LIMS](#)", 2017) is also a web-based, platform-independent LIMS. It was originally developed to facilitate NMR-based structural genomics studies. The Sesame module for metabolomics is called 'Lamp'. The Lamp module was originally designed to process NMR metabolomic analyses of Arabidopsis, although it is flexible enough to be easily adapted to other biological systems and other analytical methods.

Data Processing and Workflow Management Solutions

In metabolomics, a number of analytical techniques are typically used for analysis, with the most popular being liquid chromatography-mass spectrometry (LC-MS), gas chromatography-mass spectrometry (GC-MS) and nuclear magnetic resonance (NMR) spectroscopy. The data produced by these analytical techniques is distinct and requires different data handling methods. There is therefore the need for analysis tools and workflows designed for handling each data format.

The analysis of metabolomics data typically includes: pre-processing, annotation, post-processing (pre-treatment) and statistical analysis as stages of data processing. However, the order of processing varies based on the analytical technique used. Untargeted LC-MS data analysis is generally performed in the above order, whilst with targeted LC-MS data only metabolites of interest are measured and there is no further annotation stage. Typically, with GC-MS pre-processing and annotation are performed concurrently due to the wide availability of reference libraries. NMR is an inherently more quantitative technique than MS and when metabolites are identified they are also typically relatively quantified.

Typically for mass spectrometry data, prior to preprocessing, data must be converted into an open format e.g. mzML, mzXML and netCDF, as the majority of tools do not accept proprietary formats. Most proprietary formats can be converted to mzML or mzXML using msconvert, a proteowizard ([Chambers *et al.*, 2012](#)) project tool. For NMR, there is also an open data exchange format known as JCAMP-DX version 6.0 11, with many different vendor-dependent variants. Recently, as part of the COSMOS (COordination of Standards in MetabOlomicS) EU FP7 consortium initiative ([Salek *et al.*, 2015](#)), the XML open standard nmrML, has been introduced ([nrmML, 2017](#)).

The most popular MS metabolomics software for preprocessing is XCMS ([Weber *et al.*, 2016](#)). XCMS ([Smith *et al.*, 2006](#)) is a well established software, having first been released over a decade ago. It is a bioconductor R package that can be used for the preprocessing of LC-MS or GC-MS data. Other popular software for LC-MS data preprocessing includes mzMatch ([Scheltema *et al.*, 2011](#)), Mass Spectrometry-Data Independent AnaLysis (MS-DIAL) ([Tsugawa *et al.*, 2015](#)) and MetAlign ([Lommen and Kools, 2012](#)). Like XCMS, mzMatch is also an R package. As well as preprocessing, it additionally provides isotopic labelling analysis ([Chokkathukalam *et al.*, 2013](#)) and probabilistic metabolite annotation ([Daly *et al.*, 2014](#)). Both MS-DIAL and MetAlign are exclusively available for windows operating systems. MS-DIAL can preprocess LC- and GC- MS and tandem MS (MS/MS) data, whereas MetAlign is only able to process MS1 LC-MS and GC-MS data. For GC-MS data, AMDIS ([Meyer *et al.*, 2010](#)) (Automated Mass Spectral Deconvolution and Identification System) is the most widely used processing tool. Pure compound peaks, free of overlapping signals, are extracted by deconvoluting spectra. A user defined target library can then be used for metabolite identification. However, it is worth noting that AMDIS does not include spectral alignment.

There are also many alternative software specifically for GC-MS preprocessing, including: MetaboliteDetector ([Hiller *et al.*, 2009](#)), MET-IDEA ([Broeckling *et al.*, 2006](#)), MeltDB ([Kessler *et al.*, 2013](#)), metaMS ([Wehrens *et al.*, 2014](#)) and MSeasy ([Nicolè *et al.*, 2012](#)). Baseline correction, smoothing, peak detection and deconvolution are provided by MetaboliteDetector. MET-IDEA quantifies AMDIS outputs, also generating a list of mass spectral tags. MeltDB is a suite of molecular tools, including peak picking, retention indices calculation and sum formula annotation. metaMS is based on XCMS, but performs pseudospectra analysis to avoid the alignment stage that can be hard to execute with GC-MS.

Compared to for MS data preprocessing, there are far less tools for NMR data. Examples include Dolphin ([Gómez *et al.*, 2014](#)) and rNMR ([Lewis *et al.*, 2009](#)). Both 1D and 2D NMR spectra can be analysed by Dolphin and rNMR. Dolphin automatically quantifies a set of target metabolites. rNMR uses a regions of interest (ROIs) based approach for analysis.

Fig. 1 Metabolomics experimental workflow.

Various software tools for the annotation of preprocessed MS data provide different levels of identification. Some annotate adducts, isotopes and fragments (e.g. CAMERA [Kuhl et al., 2012](#), MZedDB [Draper et al., 2009](#)) or empirical formula (e.g. SIRIUS [Bocker et al., 2009](#)). Others automatically search metabolite databases to provide tentative metabolite candidates (e.g. MI-PACK [Weber and Viant, 2010](#), PUTMEDID-LCMS [Brown et al., 2011](#)). MS/MS or MSⁿ data can be assigned a candidate metabolite at a higher level of confidence by searching against spectral libraries acquired using authenticated chemical standards. Examples of software that perform automatic database matching includes: CFM-ID ([Allen et al., 2014](#)), CSI: FingerID ([Dührkop et al., 2015](#)) and MCID ([Li et al., 2013a](#)). MAGMa ([Ridder et al., 2013](#)) and MetFrag ([Ruttkies et al., 2016](#)) are both *in silico* fragmentation tools. Metabolite identification and quantification are often performed simultaneously for NMR data. BATMAN ([Hao et al., 2012](#); [Ravanbakhsh et al., 2015](#)) deconvolutes and quantifies ¹H NMR spectra and Bayesil ([Ravanbakhsh et al., 2015](#)) performs automatic spectral processing and identification of serum, plasma and cerebrospinal fluid (CSF) 1D ¹H NMR spectra. These tools provide different levels of identification (levels 1 to 4) as described by the Metabolomics Standards Initiative ([Sumner et al., 2007](#)).

For a more in depth look of metabolomics data handling, data processing and data analysis see reviews (Spicer *et al.*, 2017; O'sullivan *et al.*, 2011; Hoffmann and Stoye, 2012; Beiske *et al.*, 2015).

Workflows in Metabolomics

Data analysis workflows or pipelines function to provide all stages of data analysis in a single space, including sequential data processing steps provided by multiple interconnected tools. This benefits the researcher by increasing computational reproducibility and removing problems caused by lack of interoperability between tools. In metabolomics, the majority of workflows have been designed to handle LC-MS data, as it is the most widely used instrumental technique.

Workflow management systems (WMS) are platforms that provide an infrastructure where workflows can be set-up, executed and monitored. Examples of WMS that have been utilized for metabolomics data analysis include Galaxy (Afgan *et al.*, 2016), Taverna (Wolstencroft *et al.*, 2013) and Konstanz Information Miner (KNIME) (Berthold *et al.*, 2009).

Galaxy was initially designed for the analysis of genomics data, but its use has since widely expanded across many bioinformatics disciplines. The Galaxy project has three stated project goals: accessibility, reproducibility and transparency. It has been designed for ease-of-use, so that researchers without programming experience are able to run workflows without difficulty. Galaxy enables the exact replication of analysis by capturing information on all modules and parameters used. Users are able to share Galaxy workflows, histories, datasets and pages (interactive, web-based documents describing analysis), either publicly or with specific individuals, facilitating transparent research. Examples of tools that utilise Galaxy for metabolomics data analysis include Workflow4metabolomics (Giacomoni *et al.*, 2015), Galaxy-M (Davidson *et al.*, 2016) and PhenoMeNal (see Relevant Websites section).

Workflow4metabolomics 3.0 is a web-based tool that includes workflows for the analysis of LC-MS, GC-MS and NMR data. Both MS workflows consist of three analysis stages: preprocessing, statistics and annotation. In the LC-MS workflow, data are preprocessing using XCMS (Smith *et al.*, 2006) (XCMS can additionally be used for preprocessing GC-MS data). Adducts and fragments are then annotated using CAMERA (Kuhl *et al.*, 2012). Alternatively users can upload a peak list of data that has already undergone preprocessing for further analysis. Modules for filtering and batch correction can then optionally be performed. The available statistical analysis modules include both univariate (Student's *t*-test, Wilcoxon *t*-test, ANOVA, Kruskal-Wallis test, etc.) and multivariate analysis (PCA, PLS, OPLS and PLS-DA). These modules are applicable to all data types. Metabolite databases can be searched for the annotation of LC-MS data, including the Human Metabolome Database (HMDB) (Wishart *et al.*, 2013), LipidMaps Structure database (LMSD) (Sud *et al.*, 2007) and MassBank (Horai *et al.*, 2010). For GC-MS data the Golm database (Kopka *et al.*, 2005) is available for annotation, or users can upload a local database. Bruker bucketing and integration, and normalization are modules supplied specifically for NMR data.

Galaxy-M is designed for the analysis of LC-MS and DIMS metabolomics data. It provides Galaxy installations of MI-PACK (Weber and Viant, 2010), XCMS and CAMERA. Preprocessing is performed by XCMS for raw LC-MS data and SIM-stitch for raw DIMS data. Following peak picking and alignment, data can be filtered by appearance in blank samples or by removing peaks that are not present in *x*-out-of-*n* samples. In preparation for statistical analysis missing values can be imputed, and data can be normalized and transformed. For statistical analysis PCA and univariate analysis are provided. If users have the commercial MATLAB toolbox, PLS-Toolbox available, this can be installed for chemometric multivariate analysis. Tools from MI-PACK are implemented for metabolite annotation.

The PhenoMeNal App library consists of ~50 tools or apps, not including individual algorithms as some tools such as OpenMS includes multiple submodules. These tools cover analysis of a wide variety of experimental data types including LC-MS, NMR and isotopically labelled data. As well as users being able to design their own workflows with these tools, there are pre-existing workflows also available. All the tools are available via Galaxy workflows and Jupyter libraries through the Cloud Research Environment (see Relevant Websites section).

Like Galaxy, KNIME is available as a graphical user interface (GUI) with a modular environment, constructed for usability. This allows for new tools or algorithms to be easily integrated into to workflow. For metabolomics, the workflows OpenMS (Aiche *et al.*, 2015) and MassCascade (Beiske *et al.*, 2014) are available as KNIME implementations. MassCascade is specifically designed for the analysis of LC-MSⁿ data. OpenMS was originally designed for proteomics data, but has been expanded to include metabolomics data analysis (Kenar *et al.*, 2014). Similarly to MassCascade, OpenMS focuses on high resolution LC-MS data. It provides an infrastructure for the rapid development of tools. There are over 185 different tools and ready-made workflows for common MS data processing tasks (Röst *et al.*, 2016; Sturm *et al.*, 2008).

The Taverna Workflow Management System provides a suite of tools enabling users to design, edit, execute and share workflows. Publicly available workflows can be found at <http://www.myexperiment.org/>. As of 5th October 2017, searching for 'metabolomics' returns 19 workflows.

There are also some widely used tools for metabolomics data analysis that do not use WMS. These include XCMS Online (Tautenhahn *et al.*, 2012), MetaboAnalyst (Xia *et al.*, 2015) and MZmine 2 (Pluskal *et al.*, 2010). XCMS Online is an online implementation of XCMS, that includes the entire data processing pipeline for MS data, from preprocessing to metabolite identification, statistical and pathway analysis. Users can also share their data and workflows either with collaborators or publicly. MetaboAnalyst 3.0 is a web server, that contains eight independent modules for analysis, including statistical, pathway, biomarker and enrichment analysis. The majority of modules require data to have been already preprocessed using other software. MZmine 2 has a GUI and provides a toolkit of modules for MS data analysis. It is able to profile, centroid and MSⁿ data. Modules include raw data processing, peak detection and visualization.

The majority of workflows for NMR processing are written in MATLAB, including FOCUS (Alonso *et al.*, 2014) and MatNMR (Van Beek, 2007). FOCUS is specifically designed for ^1H NMR data, whilst MatNMR is more general and can process both 1D and 2D NMR data.

Metabolomics Experiments Repositories and Metabolite Databases

Metabolomics data repositories can store both raw and annotated data. Raw data can be deposited as either property data formats (e.g. Thermo .RAW, Agilent .d) or open formats, such as .mzML, .mzXML, .mzData or .netCDF. Studies in repositories can also contain lists of identified metabolites, along with their relative abundance, concentration, what spices and type of samples they are found (Salek *et al.* (2017), Haug *et al.* (2017)).

Currently there are two global repositories for metabolomics data: the European Bioinformatics Institute's MetaboLights (Haug *et al.*, 2013) and United States Government National Institute of Health (NIH) Metabolomics Workbench (Sud *et al.*, 2016). These repositories accept submissions of all types of metabolomics data. Both repositories include multiple layers, storing data and metadata from metabolomics studies along with reference libraries of metabolites.

The two layers of the MetaboLights repository are: (i) the repository, where raw data, along with annotated metadata, are stored, and (ii) the reference layer that contains a library of reference compounds (Kale *et al.*, 2016). The repository and compound library can be queried by species, instrumental analysis technology, organism part (e.g. serum, leaf) or study validation status. As of 31st August 2017 there are 279 publicly available studies on MetaboLights and 24957 compounds, with 3171 including MS spectra and 407 NMR spectra.

There is a focus of the curation of data in MetaboLights (Salek *et al.*, 2013), and it therefore has more stringent submission guidelines that Metabolomics Workbench. Experimental metadata must be submitted to MetaboLights in the ISA-TAB format (Rocca-Serra *et al.*, 2010). In order to submit a study, users must first register. There are four stages of curation a submitted study must pass through until it becomes publicly available: submitted, in curation, in review and public. During the submitted stage the submission is not yet complete and mandatory metadata is missing. When all mandatory fields are complete curators will appraise the study, looking for any missing optional fields or errors not detected by automatic validation (Kale *et al.*, 2016). When curation is finished, the submitter is given a read-only reviewer link that can be shared with a journal or collaborators. The study will not become public until a submitter specified publication date has been reached. The analysis tools section of MetaboLights is currently under development. A new tool that plots study factor distribution using parallel coordinates is in the beta development stage.

Compared to MetaboLights, Metabolomics Workbench provides greater analysis capability. Data in publicly available studies can be normalized, clustered, and univariate and multivariate statistical analysis (PCA, linear discriminate analysis and PLS-DA) can be performed. For MS data additional analyses are provided: classification and feature analysis, pathway mapping, MS search for metabolite identification and comparison of metabolites between studies (meta-analysis). Users also have the option of performing statistical analysis on their own uploaded dataset.

There are 440 publicly available studies in Metabolomics Workbench as of October 2017. Bubble plots classifying studies by disease, sample source, species, pathway or metabolite class allow users to select a specific subset of studies. Metabolomics Workbench also provides a REST service where HTTP requests can be used to access data and metadata, including metabolite structures and experimental results. The Metabolomics Workbench Metabolite Database stores metabolite structures and annotations. It contains >61,000 entries collected from public databases including LIPID MAPS (Sud *et al.*, 2007), ChEBI (Hastings *et al.*, 2013), HMDB (Wishart *et al.*, 2013), BMRB (Ulrich *et al.*, 2008), PubChem (Kim *et al.*, 2016) and KEGG (Kanehisa *et al.*, 2012). Users can employ either text based search or m/z value from untargeted MS search to search for metabolites.

To submit a study to Metabolomics Workbench, users must register and obtain authorization. Once this has been completed (i) the study is registered, (ii) users must submit metadata in the specified format, either via an online form or a supplied excel template and (iii) raw data and/or supplementary material must be uploaded. It is encouraged that common names from the RefMet (A Reference list of Metabolite names) database are used for annotation.

The Global Natural Products Social Molecular Networking (GNPS) (Wang *et al.*, 2016) platform provides analysis and storage of natural products mass spectrometry data. Data are stored in the Mass Spectrometry Interactive Virtual Environment (MassIVE) repository, originally developed for proteomics studies (Perez-Riverol *et al.*, 2015). Compared to other repositories, GNPS is unique in providing continuous metabolite identification for MS/MS spectra, with data sets being reanalysed for new identifications once a month. Unlike other repositories GNPS has no requirements for reporting experimental metadata.

As well as the global metabolomics repositories, there are also a number of smaller, more specific repositories. These include Metabolomics Repository Bordeaux (MeRy-B) (Ferry-Dumazet *et al.*, 2011) and Metabolic Phenotype Database (MetaPhen) (Carroll *et al.*, 2010, 2015). MeRy-B is a repository specifically designed for plant ^1H NMR data, but also contains GC-MS data.

MetaPhen is a data repository that is available as part of MetabolomeExpress, a GC-MS metabolomics data analysis platform. It contains a variety of tools for the analysis of the publicly available data, including ResponseFinder, MetaAnalyser, PhenoMeter, and MSRI Library manager. Users can directly search for metabolites of interest using ResponseFinder, which includes search by species and organ/tissue/fluid type. MetaAnalyser performs meta-analysis by comparing the results of multiple experiments, plotting heatmaps of aligned and clustered data. PhenoMeter allows users to search the reference library via metabolite response patterns.

The MetabolomeXchange (see Relevant Websites section) consortium is based on the successful ProteomeXchange (Vizcaino *et al.*, 2014). It serves as a data aggregator, collecting studies from the MetaboLights, Metabolomics Workbench and MeRy-B repositories. Users have the option of subscribing in order to be notified about new datasets or updates to existing datasets.

OmicsDI is an open-source platform based at EMBL-EBI, that captures and integrates proteomics, genomics, metabolomics and transcriptomics datasets (Perez-Riverol *et al.*, 2016). For metabolomics the data repositories: MetaboLights, GNPS, MetaPhen and Metabolomics Workbench, are included. Since different repositories use different data models, ontologies, metadata representation and identifiers, OmicsDI uses metadata normalization and annotation expansion to harmonise searching across the various resources. Users are therefore able to discover multi-omics datasets that are linked to publications, as well as similar experimental datasets, suggested by metadata matching.

Most omics, including metabolomics, aim to follow FAIR principles by making data Findable, Accessible, Interoperable and Reusable (Van Rijswijk *et al.*, 2017; Wilkinson *et al.*, 2016). The data handling, analysis tools, data standards and resources discussed here should help users to adhere to FAIR principles.

Metabolomics Databases

The substantial growth of the field of Metabolomics during the past decade has instilled a need for sharable resources. Amongst other resources such as publicly available data processing softwares and workflow pipelines, data repositories, libraries and databases that store experiment and metabolite related information have been on the rise.

As detailed above, public repositories such as MetaboLights (Salek *et al.*, 2013) and the Metabolomics Workbench (Sud *et al.*, 2016) attempt to capture the data output of the entire workflow of a metabolomics experiment. These repositories store information on the experimental design, details on projects, experiments and samples as well as all the instrument generated raw data and the processed data of experiments. Commercial and public libraries and databases store exhaustive details about metabolites such as their physicochemical properties, related structures and links to other databases. Metabolite databases can be divided into three categories, a) metabolite mass spectral databases, b) Species-specific metabolite databases and c) metabolic pathway databases.

Metabolite mass spectral databases

Once the raw data is acquired from the instruments, data processing softwares are used to convert the raw data into a data matrix of molecular features with measures of their abundance in the samples. One of the last step in processing of raw data is to identify these molecular features as specific metabolites and this identification is performed using metabolite spectral libraries or databases. Metabolite spectral libraries store information on the physicochemical properties of metabolites such as molecular name, molecular weight, chemical formula, structure information, retention time, high-quality spectral data and links to external databases. Currently, there are several mass spectral libraries available for metabolomics.

NIST 17 ("NIST Standard Reference Database 1A v17", 2017) is the latest mass spectral database release of the National Institute of Standards and Technology, USA. NIST 17 contains an Electron Ionization (EI) mass spectral library of over 306,000 spectral belonging to over 267,000 unique compounds, a Gas Chromatography (GC) data library with over 404,000 retention index values for over 99,000 compounds covering both polar and nonpolar columns and an MS/MS library of over 650,000 spectra of over 14,000 compounds. It also includes the NIST MS search software for searching and identifying compounds and the automated mass spectral deconvolution and identification system (AMDIS) software used for deconvoluting chromatograms. The Wiley Registry of Mass Spectral Data is one of the largest collection of EI mass spectra. The 11th edition of Wiley ("Wiley Registry of Mass Spectral Data, 11th Edition", 2017) stores about 775,500 mass spectra for over 599,000 unique compounds and over 740,000 searchable structures. Massbank (Horai *et al.*, 2010) is a public repository that stores mass spectral data of high-resolution MSⁿ spectra. It is a distributed database in the sense where participating research groups are able to submit mass spectral information from local MassBank data servers. Users are then able to access spectral information from multiple groups through Massbank's web interface. Currently Massbank stores over 41,000 spectra. The METLIN Metabolite Database (Smith *et al.*, 2005) is a repository of MS and MS/MS data that stores details of more than 961,000 molecules. In addition, it also stores over 200,000 high-resolution in silico MS/MS spectra. The Golm Metabolome Database (Kopka *et al.*, 2005) stores information of EI mass spectra and associated retention indices of peaks quantified by GC-MS. The Madison-Qingdao Metabolomics Consortium Database (MMCD) (Cui *et al.*, 2008) is a library that stores details of metabolites analysed through NMR and MS. MMCD currently contains details of over 20,000 compounds. The Spectral Database for Organic Compounds (SDBS) ("SDBSWeb", 2017) stores mass spectrum information for around 34,000 organic compounds. The different types of spectra it stores are electron impact Mass spectrum (EI-MS), Fourier transform infrared spectrum (FT-IR), ¹H nuclear magnetic resonance (NMR) spectrum, ¹³C NMR spectrum, laser Raman spectrum, and electron spin resonance (ESR) spectrum.

Species-specific metabolite databases

The Human Metabolome Database (HMDB) (Wishart *et al.*, 2013) is a public repository containing detailed information about metabolites found in the human body. HMDB currently stores more than 330,000 spectra, stores details of more than 114,000 metabolites and has information derived from 17 different biofluids. HMDB is designed to contain or link externally to chemical data, clinical data and biochemistry data. The KNApSACk family databases (Nakamura *et al.*, 2014) are an integrated metabolite-plant species databases for multifaceted plant research. It currently has over 111,000 species-metabolite relationships

encompassing 22,350 species and over 50,000 metabolites. The RIKEN MSn spectral database for phytochemicals (ReSpect) (Sawada *et al.*, 2012) stores plant-specific MS/MS spectral data. ReSpect currently stores around 9000 spectral records.

Metabolic pathway databases

Metabolic pathway databases store information on biochemical pathways and the various enzyme reactions along the pathways. In addition, they store data on genes, gene products and compounds that are part of these reactions along with links to external databases on further information on the participants.

The KEGG Pathway Database (Arakawa *et al.*, 2005) is a collection of manually drawn pathway maps detailing metabolic reactions and the resulting molecular interactions. KEGG is a collection of fifteen databases that are divided into four categories: Systems Information, Genomic Information, Chemical Information and Health Information. The KEGG PATHWAY database that stores metabolic maps currently contains 519 pathway maps totalling to more than 530,000 different pathways and are detailed under the Systems Information category.

The MetaCyc database (Caspi *et al.*, 2016) stores information on metabolic pathways and enzymes that are experimentally determined and are curated from scientific literature. The database stores pathways for a wide range of organisms and currently contains 2572 pathways from 2844 different organisms. MetaCyc is widely used as the online encyclopaedia of metabolism, used to predict metabolic pathways in sequenced genomes and also used in metabolic engineering.

BioCyc (Caspi *et al.*, 2016) is a collection of pathway and genome databases for organisms whose genomes have been sequenced. Each of these databases contain the full genome, predicted metabolic network and additional information on enzymes, reactions and predicted operons. The BioCyc database also includes the Pathway Tools Software, a symbolic systems biology software system. The tools allow the creation of new pathway and genome database, has options to query visualize and analyze the databases, supports the development of metabolic flux models and allows the interactive editing of the underlying genome databases.

The Reactome pathway knowledgebase (Fabregat *et al.*, 2016) is a manually curated database of pathways. Reactome's pathways are peer reviewed where experts and the Reactome editorial staff work together in finalising the contents and are cross-referenced to other bioinformatics resources such as NCBI Gene, Ensembl, UniProt, KEGG Compound, PubMed and Gene Ontology. Reactome also provides pathway analysis tools that performs ID mapping, pathway assignment and enrichment analysis.

The Plant Metabolic Network (Kruger and Ratcliffe, 2012) is a collection of one multi-species reference database called PlantCyc and 76 species/taxon-specific databases. PlantCyc currently contains more than 1000 pathways and compounds from over 350 plant species. The pathways have been manually curated from literature and also includes hypothetical pathways and computationally predicted pathways that are published in peer-reviewed journals.

Statistical Analysis and Functional Interpretation

The widespread adoption of metabolomics in basic research and large-scale clinical investigations have resulted in the generation of increasingly complex data sets. Making sense of such high-dimensional data requires a good understanding of modern statistical and functional analysis approaches. In the previous sections, we have described experimental design, raw data processing, databases and data repositories. In this section, we will introduce the key concepts and main approaches commonly used in statistical analysis and functional interpretation of metabolomics data.

Data Input

The standard input for statistical data analysis is a high-dimensional data matrix with variables in rows and samples in columns (or its transposed format). Such data can be produced from most metabolomics data processing tools (Smith *et al.*, 2006; Pluskal *et al.*, 2010; Hao *et al.*, 2012; Ravanbakhsh *et al.*, 2015; Tautenhahn *et al.*, 2012). For data from targeted metabolomics, variables are compound IDs; and for untargeted metabolomics data, variables are typically peak locations or spectral bins. Data dimension refers to the number of variables in the matrix, which can vary from 100s to 1000s, with untargeted metabolomics data typically containing more variables. Samples are biological replicates associated with class labels or other metadata reflecting experimental designs. Quality control (QC) samples are often included for quality assurance during analysis.

Data Cleaning

The first, but often neglected step in metabolomics data analysis, is data cleaning or data filtering. Data from comprehensive metabolomics experiments usually contains a large amount of noise that can negatively impact downstream data analysis. Proper data cleaning will not only improve data quality, but also enhance statistical power and reduce false positives (Bourgon *et al.*, 2010). To identify low-quality data for cleaning, several empirical rules are frequently used, including a) hard-to-measure variables such as those close to baseline noises or showing large variations in QC samples or technical replicates; b) uninformative variables that are relatively constant throughout the experimental conditions based on their inter-quantile ranges, standard deviations, etc.; and c) outlier samples with extreme deviations from the main clusters. As outliers could be generated by unexpected but biologically important processes, their exclusion should be better justified with technical or experimental reasons, in addition to visual inspections.

Data Normalization

This step aims to reduce overall undesirable variations in the data to facilitate biologically and statistically meaningful comparisons. As different analytical platforms are currently used in metabolomics, a wide variety of normalization methods have been developed over the past decade (Van Den Berg *et al.*, 2006). Some of them are generic statistical methods such as log transformation and auto-scaling; while others are biologically motivated approaches such as the probabilistic quotient normalization that was initially developed to address the dilution effects in NMR-based metabolomics on urine samples (Dieterle *et al.*, 2006). The MetaboAnalyst web server currently supports a comprehensive selection of 13 different normalization methods (Xia and Wishart, 2016; Xia *et al.*, 2015). A new web-based tool, NOREVA allows users to evaluate the effects of 24 normalization methods for MS-based metabolomics data (Li *et al.*, 2017). No consensus has been reached on the best normalization methods for metabolomics data. In general, we should start with simple methods with minimal transformations of the original data. More complicated approaches may be necessary for complex data from large-scale studies.

Unsupervised Methods

After cleaning and normalization, the data is now suitable for statistical analysis. The first step is to examine if there are any interesting patterns or trends in the data, and whether these patterns are likely to be technical artifacts or biological effects. Unsupervised methods are designed for such tasks. As the name suggests, these type of methods use only the data (X) itself without considering the class labels (Y) during the analysis. Here we will introduce two main approaches - principal component analysis (PCA) and cluster analysis. PCA is the most widely used method in metabolomics for data overview and pattern discovery. PCA is a dimensionality reduction method which aims to capture the most variation of the data in the top few principal components (PCs) created by linear combinations of the original variables. These PCs can be visualized as a 2D or 3D scatter plot (also known as scores plot) to see if there are major grouping patterns among samples. The corresponding loading plots can be used to identify the variables that contribute to such separation patterns. In addition to PCA, cluster analysis (or clustering) is also widely used to help reveal inherent patterns in data. These type of methods work by first computing similarities or distances among samples or variables, and then assigning them to different clusters so that items within the same cluster will be more similar to each other than they are to those outside the cluster. The result of the cluster analysis can often be visualized in heatmaps, a technique that uses color gradients to represent data values. In clustered heatmaps, main patterns or clusters will stand out as distinct “patches” displaying more homogenous colors as compared to the surrounding background. Several clustering methods are often used in metabolomics data analysis, including hierarchical clustering, k-means clustering, self-organizing maps (SOM), etc. More detailed introductions on these clustering algorithms can be found in this excellent review paper (Ren *et al.*, 2015).

Supervised Approaches

These methods are used to formally evaluate the associations between the variations in data (X) and class labels (Y). Metabolomics has a long history of using various multivariate statistical methods and machine learning algorithms for classification and regression analysis (Broadhurst and Kell, 2006). Here we will introduce a widely used multivariate statistical method - partial least squares discriminant analysis (PLS-DA), and then briefly comment on a powerful machine learning method - support vector machine (SVM). Similar to PCA, PLS-DA is a dimensionality reduction method by creating latent variables (LV) through linear combinations of original variables in the data (X). These LVs are computed by referring to the class labels (Y) to maximize the explained variance in Y in the top few LVs. The PLS-DA results can also be visualized in scores and loadings plots for interpretation. Due to the supervised nature of the method, the performance (as seen from the separation patterns in the scores plot) is usually much better compared to PCA. However, this may be misleading. It has been shown that PLS-DA can produce good separation patterns even with randomly generated group labels (Westerhuis *et al.*, 2008). Therefore, PLS-DA is very susceptible to “over-fitting” – a well-known issue associated with using supervised methods. To address this issue, results from PLS-DA need to be evaluated using both cross-validations (or double cross-validation if sample size is sufficient) and permutation tests. In cross-validation, samples are divided into trainings and testing groups, and the training group is then used to build PLS-DA models whose performances are evaluated using the test group. The permutation tests evaluate whether similar performances can be obtained using models created based on randomly labelled data, compared to the model created using the original group labels. SVM is a powerful machine learning method commonly employed in metabolomics data analysis (Mahadevan *et al.*, 2008; Heinemann *et al.*, 2014). The algorithm uses kernel functions to map the original data to a higher dimensional feature space and separating it by means of a maximum margin hyperplane (Noble, 2006). Compared to PLS-DA, SVM generally gives better performance and is less susceptible to over-fitting issues. However, the interpretation of the underlying models is very complicated and much less intuitive (i.e. black box).

Functional Analysis

Direct functional analysis is generally limited to data from targeted metabolomics. For untargeted metabolomics, researchers need to first identify significant peaks or spectral bins, and then annotate the underlying metabolites before performing functional analysis. A key concept in functional analysis is that the unit of analysis has been shifted from individual metabolites to a set of

metabolites (termed a metabolite set). Metabolite sets are groups of metabolites that share a particular property, for instance, a group of metabolites involved in the same pathways, altered in the same diseases, or associated with the same genetic or epigenetic variations. If particular metabolite sets are significantly enriched in the data, the corresponding shared properties (i.e. pathways) are considered to be relevant to the experimental conditions of interest. Many different algorithms have been developed to perform enrichment tests. For instance, the over-representation analysis (ORA) methods accept a list of significant metabolites and evaluate whether certain metabolite sets appear more often than expected by chance, using Fisher's Exact tests or hyper-geometrics tests. For instance, the Metabolites Biological Role (MBROLE) web application uses hypergeometric tests to perform comprehensive functional enrichment analysis (Lopez-Ibanez *et al.*, 2016). The quantitative enrichment analysis (QEA, also known as functional class scoring) is a relatively new approach for enrichment tests. Compared to ORA, QEA utilizes the complete data to calculate enrichment scores for individual metabolite sets, and is more sensitive for detecting subtle but consistent changes. A wide range of QEA tools are available, showing many statistical and practice differences (Tarca *et al.*, 2013). For instance, the QEA module in MSEA (now part of MetaboAnalyst) is based on the *globaltest* R package (Goeman *et al.*, 2004; Xia and Wishart, 2010). Detailed discussions on the performance characteristics and statistical properties for these different approaches can be found in a recent excellent review paper (De Leeuw *et al.*, 2016). Due to the inherent analytical bias in metabolomics platforms and the limited metabolome coverage, results from current enrichment analysis should be interpreted with caution.

From Peaks to Biological Activities

The increased application of sensitive and high-resolution MS-based metabolomics makes it possible to perform functional analysis directly from raw spectral peaks. The key idea is to redefine the metabolite sets using the spectral features of the corresponding metabolites, and then evaluate the enrichment of these chemical signals directly from spectral peaks without formal compound identification. The *mummichog* method is the first bioinformatics approach in this direction (Li *et al.*, 2013b). The algorithm accepts two lists of spectral peaks - a significant peak list obtained through statistical analysis (i.e. *t*-tests) and a reference peak list (i.e. all peaks detected in the experiment). It computes matching scores for different pathways from the significant peak lists, and enrichment *p*-values are calculated by comparing the scores to those obtained using peak lists of the same size, but randomly drawn from the reference peaks. Further development in this direction holds the potential to greatly facilitate metabolomics functional analysis.

Due to space limitations, this section covers only those most common methods used in statistical and functional analysis of metabolomics data, while ignoring very basic methods such as univariate statistics (i.e. *t*-tests and ANOVA) for the detection of significant variables. For the same reason, we have also intentionally omitted some advanced topics including biomarker analysis and time-series data analysis. Readers are referred to several comprehensive reviews and tutorials for more detailed discussions on these topics (Broadhurst and Kell, 2006; Smilde *et al.*, 2010; Xia *et al.*, 2013; Worley and Powers, 2013; Ren *et al.*, 2015). Most of these concepts and procedures have been implemented and are available thorough easy to use and freely accessible XCMS online and MetaboAnalyst web applications.

Mass Spectrometry-Based Metabolomic Analysis

Russell Pickford, University of New South Wales, Kensington, NSW, Australia

© 2019 Elsevier Inc. All rights reserved.

Introduction

Metabolites are the intermediates and end products of biological metabolism, the definition typically being limited to small molecules such as amino acids, sugars and lipids.

The field of metabolomics aims to measure metabolites within biological samples to obtain profiles or ‘metabolomes’. These can be compared across sample types – different disease states or gene knockouts for example – to learn more about the underlying biology or to find metabolites which can be used to recognise or define the disease state – biomarkers.

The term ‘metabolome’ was defined as “the complete set of metabolites/low-molecular-weight intermediates, which are context dependent, varying according to the physiology, developmental or pathological state of the cell, tissue, organ or organism” (Oliver, 2002).

Metabolomics is somewhat of an ancient science – ants were used by the ancient Chinese (2000–1500 BC) to detect high levels of glucose in urine – and hence diabetes. Currently, Doctors often test a panel of metabolites within patient’s blood – for example glucose or cholesterol – to ensure that they are within a normal range. These are examples of targeted metabolomics.

Science is now aiming to study organisms as integrated systems to obtain as complete a picture as possible. This systems biology approach combines experimental data from a range of ‘omics experiments’:

- Genomics measure the DNA, a ‘blueprint’ for the organism.
- Transcriptomics measure the RNA transcripts produced by the genome under specific circumstances. Proteomics measures the proteins produced under these circumstances, including metabolic enzymes.
- Metabolomics measures the small molecules or metabolites of the system.

As the final downstream product, the metabolome can be considered the closest reflection of the phenotype (Kell et al., 2005).

The analytical chemistry measurements and subsequent data analysis required to examine a metabolome are complex. Trying to simultaneously measure many different metabolites of widely-varying properties – such as concentration, molecular weight and polarity – is very difficult. No current analytical technique can measure an entire metabolome within a single experiment, or perhaps even with a combination of experiments.

The two techniques most frequently used for metabolomic analysis are mass spectrometry (MS) and Nuclear Magnetic Resonance (NMR). Both have advantages and disadvantages.

NMR has a much poorer detection limit and so can measure fewer metabolites, but is fast, simple and non-destructive to the sample. Also, metabolites observed can almost always be identified from the rich data obtained.

Mass spectrometry is more complex experimentally, destructive to the sample and identification of detected species can be a major challenge.

MS does however offer some key strengths:

- wide dynamic range – the ability to simultaneously measure analytes of very different concentrations, important as the range in biological samples can be many orders of magnitude.
- high sensitivity – the ability to measure analytes at very low concentration.
- reproducible, quantitative analysis – the signal from a metabolite is proportional to concentration.

Data analysis of metabolomics data acquired using mass spectrometry relies on a good understanding of how the data is generated and what information it can and cannot provide. Data analysis ranges from simple univariate statistics to complex manipulations and clustering algorithms.

Instrumentation Employed for Mass Spectrometry-Based Metabolomics

Mass Spectrometry

A mass spectrometer is an instrument that measures the molecular weight and abundance of molecular species within a sample.

The instrument consists of several functional stages (Fig. 1):

- Ionisation
- Mass Analysis
- Detection

Manipulating and detecting molecules with a mass spectrometer requires them to be charged. Neutral species cannot be observed. Thus, the first part of mass spectrometry analysis is ionisation. This stage converts neutral species into gaseous charged ions which can then be manipulated, measured and detected.

Fig. 1 Schematic detailing the major components of a mass spectrometer.

There is no universal ionisation procedure – different choices here will allow observation of different panels of analytes, but hide others.

Choices of ionisation are typically electrospray (ES) (Fenn *et al.*, 1989; Gaskell, 1997) and atmospheric pressure chemical ionisation (APCI) (Carroll *et al.*, 1974; Byrdwell, 2001) for solution phase analysis and electron ionisation (EI) (Bleakney, 1929) or chemical ionisation (CI) (Munson and Field, 1966) for gaseous analysis. ES, APCI and CI are ‘gentle’ ionisation methods which generally send an intact cationised molecule into the mass analyser. This is important as fragmentation during ionisation can greatly complicate the data produced. EI however produces a radical cation which then usually fragments, sometimes so completely that the intact precursor molecule is not observed.

Except for EI, which only produces positively-charged species, each can be employed in positive or negative polarity. The choice of polarity will again allow observation of different analytes. For example, basic species generally are easier to observe in positive mode and acidic species in the negative mode as they will easily become charged by gaining or losing a proton respectively.

The generated ions are directed into a mass analyser where they are sorted by molecular weight (really mass to charge ratio, m/z). All mass analysers require a vacuum to be functional and operate using a combination of electric fields and (less frequently) magnetic fields to manipulate the ions.

Mass analysers can be divided into two main categories – low resolution and high resolution. Resolution refers to the ability to discriminate analytes which are close in m/z .

Low resolution mass analysers include linear quadrupoles (Douglas, 2009) and quadrupole ion traps (March, 2009), typically operating at unit resolution – they will discriminate mass 100 from mass 99 and mass 101.

High resolution mass analysers include Time-of-Flight (Boesl, 2017), Fourier Transform Ion Cyclotron Resonance (Marshall *et al.*, 1998) and Orbitrap (Zubarev and Makarov, 2013). These are a finer toothed comb – they will separate mass 100.0 from 99.9 and 100.1, and potentially much finer than this – allowing measurement of molecular weight much more accurately and discrimination of species of very similar molecular weight.

Mass analysers should however not be judged by resolution alone. Each has specific advantages and disadvantages and are employed for different experiments (Brune, 1987). For example, advantages of quadrupoles include high transmission, robustness, tolerance of higher pressures and low cost.

When looking for specific targets and requiring high sensitivity then a quadrupole is an excellent choice. When screening samples for as many metabolites as possible then resolution and mass accuracy become important, therefore Time-of-Flight or FT-ICR or Orbitrap are ideal for these profiling experiments.

Different mass analysers and combinations thereof allow different experiments to be performed.

The final component is detection – the abundance of each ion is measured, and a mass spectrum produced. The mass spectrum is a 2D plot with m/z on the x-axis and abundance on the y-axis. The units of the abundance axis vary with instrument, with detector and with manufacturer. It is frequently scaled to ‘relative abundance’ where the most intense signal in the spectrum is assigned 100% and the other signals shown relative to this (Fig. 2).

Separation Techniques

Whilst direct analysis of complex samples is possible, it is generally preferable to ‘hyphenate’ the mass spectrometer with a separation technique. This separates the components in time and space according to some chosen physical property, therefore simplifying the mass spectra obtained at any individual time point. Addition of a separation technique also facilitates automated analysis as well as providing potential enhancements such as potential discrimination of isomeric species (which have the same molecular weight but different structure) and enhancement of signal due to decreased competition during ionisation.

Gas chromatography (GC) is typically employed where the analytes are heat stable and volatile (for example gas, flavour, fragrance analysis) or can be made volatile using simple chemical derivatisations.

Samples are injected into a hot liner where they are vaporised and then directed through a fused-silica column using a carrier gas (mobile phase). Interactions between the analytes and column surface (stationary phase) will differ based on their chemistry, so that some are retained longer and some shorter as they pass through to the detector – providing separation in time. GC separations can be tuned and optimised using column chemistry and column temperature.

Fig. 2 Mass Spectrum obtained from electron ionisation of a mixture of nitrogen and carbon dioxide gases.

Liquid chromatography (LC) is typically employed for involatile analytes (for example amino acids, sugars, lipids) and does not generally require any prior chemical derivatisation. This makes it a popular choice for untargeted metabolomics as the sample preparation is minimal, reducing experimental bias.

Samples are injected into a stream of liquid – mobile phase – and pass through a stainless-steel or plastic column packed with silica beads derivatised to some specific functionality.

For example, C18 columns are widely used and have an 18-carbon hydrocarbon chain attached to the beads. This provides a hydrophobic surface (stationary phase) for the analytes to interact with as they pass through, therefore non-polar analytes will have a strong interaction with this surface and be retained longer than polar analytes. LC separations can be optimised using a wide range of parameters such as column chemistry, choice of mobile phase solvents and temperature.

Less frequently used, but no less useful, is capillary electrophoresis where analytes are separated by charge and mobility within a buffer solution as they move down a fused silica capillary under the influence of high voltage.

GC–MS and LC–MS

During these analysis methods the output of the separation device is connected to the ionisation source of the mass spectrometer. The output is continuously ionised, and the ions produced directed into the mass spectrometer. Mass spectra are recorded, typically every second or so, throughout the whole run time. The data therefore consists of several hundred to thousand consecutive mass spectra – it is now a 3D plot with the axes of time, m/z and abundance. This can be visualised as an ‘ion map’ with time and m/z as the axes and intensity of colour as the abundance (**Fig. 3**).

The use of mass spectrometry as a detector places some limits on what can be used for the separation part of the experiment – for example LC–MS mobile phases and sample components need to be volatile – salts cannot be used.

Tandem Mass Spectrometry – MS/MS

Mass spectra generated by ES, APCI and CI generally only contain intact cationised analytes, yielding the molecular weights of the compounds within the sample. An extra dimension of information can be obtained using tandem mass spectrometry. This process is performed within the mass spectrometer and involves a specific precursor ion (m/z) being isolated and fragmented, normally via collisions with a neutral gas such as nitrogen or argon. These product ions are then detected and can yield a ‘fingerprint’ helping to identify the analyte. Two analytes can have identical molecular weight – isobaric species – but very different MS/MS fingerprints and can therefore be discriminated by MS/MS but not by MS (Yost and Fetterolf, 1983; de Hoffmann, 1996).

The tandem mass spectrum produced from MS/MS analysis of the precursor ion at m/z 784 is shown (**Fig. 4**). Some remaining (unfragmented) precursor can be observed together with a large product ion at m/z 184. This ion is structurally diagnostic – it is formed from lipid molecules containing a choline group and therefore yields information that the precursor at m/z 784 is a phosphatidylcholine.

The use of MS/MS can add an additional dimension to the data if employed together with MS scans, such as in the case of profiling experiments. The data now contain a time component and both MS and MS/MS scans.

Fig. 3 Ion map obtained from LC-MS analysis of a plasma lipid extract.

Fig. 4 Tandem mass spectrometry instrument components and MS/MS spectrum.

When performing untargeted or profiling experiments the analyte masses are not known. Automated, rules-based approaches are therefore employed to select precursor ions for MS/MS analysis. For example, a full MS 'survey' scan performed and then consecutive MS/MS scans on the 6 most intense species in this survey scan, and the cycle repeats throughout the run. Rules can be added – to include or exclude selected masses or charge states for example. This is generally termed data-dependent analysis – DDA ([Mann et al., 2001](#)).

Performing MS/MS with a very wide mass selection window is becoming popular, for example simultaneously fragmenting everything over the mass range 150–250 Th. These have less specificity and the data are harder to interpret since the connectivity between precursor and product ions is no longer certain. They do however provide much greater MS/MS coverage. This approach is termed data independent analysis – DIA ([Doerr, 2014](#)), MS^E ([Plumb et al., 2006](#)) and SWATH ([Gillet et al., 2012](#))

Mass Spectrometer Data Files

The data structure remains similar, but each instrument manufacturer produces their own data format – .d from Agilent, .wiff from Applied Biosystems and .raw from ThermoFisher Scientific for example.

These formats are proprietary and need to be analysed within the vendor's own software or be converted to a community format such as NetCDF ([Unidata, 2016](#)), mzDATA ([Orchard et al., 2007](#)) or MzXML ([Pedrioli et al., 2004](#); [Lin et al., 2005](#)). Since 2008 the community has largely deprecated prior formats and adopted mzML ([Deutsch, 2008](#)) as the unified standard. These formats are readable and accessible to freeware or web-based data processing tools. Open-source tools such as ProteoWizard ([Kessner et al., 2008](#)) can be employed to batch convert files from proprietary to open source.

General Considerations for Metabolomics Experiments using Mass Spectrometry

Experimental Design

The experimental design is important to consider prior to any practical work being performed. The design will depend upon the statistical rigour required (power analysis) as well as the experimental goals and practical limitations. If we are comparing changes across two sample types, then large changes in metabolite concentration are easier to see and have confidence in. Small changes require much more rigour to be able to observe confidently.

Replication is important – technical replicates are repeat analyses of the same sample which allow the variability of the measurement to be calculated. Biological replicates allow the natural variability of the target metabolites within a sample set to be examined. These are both very important – if the target analyte varies 10% between test and control but varies 20% within control then it is very hard to draw any confident conclusions about the result. Acceptable minimum standards for replication vary between scientists and experiments. The data is generally assessed using at least mean and standard deviation (coefficient of variation). These require a normal distribution of data and therefore at least 6 replicates to describe this. Generally, more is better!

It is also important to randomise the samples during instrumental acquisition. The instrument's performance can change over time and the effect of this on the data needs to be minimised, so the comparison is really between test vs control and not data from clean instrument vs data from dirty instrument. For the same reason all samples should be run in a single batch and not on different days.

There are many confounding variables when dealing with biological samples, which must be controlled as much as possible. The experiment may be testing the blood of cancer patients vs healthy patients, but not all differences observed will be due to the cancer. Metabolite profiles can vary for many reasons, for example, age, sex, race, obesity, exercise.... Even diet is an influence as what is eaten makes its way into the blood, this is one reason that pathology labs prefer to take patient blood in a fasted state.

It is therefore important to know about the variability in the sample population, and control as best possible. It is no good looking for a cure for cancer and instead finding a biomarker that differentiates males from females.....

Sample Preparation for Mass Spectrometry Analysis

Preparing the biological sample so that it may be analysed by mass spectrometry is a key part of metabolomics experiments ([Raterink et al., 2014](#)). The sample preparation will have a large effect on the result – changes to sample preparation will change the metabolites observed in the experiment.

The general principle is to extract the metabolites from the sample with as light a touch as possible. For example, urine metabolomics may just require a simple dilution, plasma will require protein precipitation and tissue will require homogenisation and extraction.

If the experiment is targeting a metabolite or panel of metabolites then the sample preparation can be optimised experimentally – choices of solvents, pH, volumes etc can all be optimised for maximum signal. A preconcentration step such as solid phase extraction may also be employed. If the experiment is untargeted then the extraction and preparation normally seek to extract as wide a range of metabolites as possible with as little perturbation to the sample as possible.

Targeted Metabolomics

Targeted metabolomic experiments seek to accurately quantify specific metabolites within a sample (Roberts *et al.*, 2012; Griffiths *et al.*, 2010; Koal and Deigner, 2010). They target a limited number of analytes. For example, to observe what happens to the concentration of a drug in a patient's body over time only detection of this drug is required. To study heart disease a panel of key analytes involved in cardiovascular metabolism may be chosen (Griffin *et al.*, 2011).

Only the targeted analytes are observed in the data, the rest of what is happening with the sample is hidden. This is therefore a trade off, achieving excellent data concerning one panel of metabolites but no data about the rest of what may be happening with the sample.

Absolute quantification obtains the amount of analyte within a sample, normally measured in moles or by weight, for example nanograms analyte per gram of tissue.

Quantification with mass spectrometry is performed by regression analysis of a calibration curve plotting signal against concentration, therefore an authentic standard is required for every individual compound quantified. Internal standards are employed to correct for experimental error, these are generally isotopically-labelled (C13, N15) analogues of the analyte, or close structural analogues which are known not to be contained in the sample, again with each analyte ideally having its own internal standard (Green, 1996).

It is possible to perform relative quantification across samples and sample sets when authentic standards are not available, however the results are reported only as a fold-change difference in peak areas obtained, which is difficult to draw biologically-relevant conclusions from. Typically, untargeted metabolomics will produce relative quantification results and then the more interesting changes can be confirmed and more accurately characterised using targeted experiments.

Data Characteristics of Targeted Metabolomics Experiments

The data output of the mass spectrometer during targeted quantification experiments is a plot of signal (relative abundance) against time for each analyte (Fig. 5). The signal can be from the intact analyte – normally termed Selected Ion Monitoring – or from a selected fragment ion produced by MS/MS of the analyte – normally termed Selected Reaction Monitoring. The fragment ion is selected to optimise for sensitivity and specificity.

The plot is then integrated, and the area of the peak produced by the sample signal recorded. Integration is performed in an automated manner with each mass spectrometry vendor providing their own set of algorithms. The shape of the peaks produced are somewhat variable with analyte and with separation method, therefore the integration process requires some manual checking and tuning to do the best job possible.

9	Unknown Sample	20.00	1.2	0.107	ng on column

Fig. 7 Part of an output table after LC-SRM quantitative analysis.

Metabolite Quantification

A calibration curve is obtained by regression analysis after plotting the peak area against concentration for a known set of standard concentrations ([Fig. 6](#)). If an internal standard is used for normalisation, then the plot becomes (peak area standard/peak area internal standard) vs concentration.

The concentration of the analyte is calculated using regression analysis of the standard curve – the peak area obtained is transformed into concentration.

Data Analysis

Targeted metabolomic data ([Fig. 7](#)) is typically analysed in a spreadsheet using univariate analysis – the comparison of a single variable (analyte amount) between samples and sample sets ([Vinaixa et al., 2012](#)). For example, the amount of glucose in the blood of diabetics vs healthy individuals.

Analysis is normally performed with replicates – both biological and technical. Therefore, a mean and a standard deviation or coefficient of variation are the required outputs. Outliers can be removed to improve the data quality after appropriate analysis, although this requires much care – the sample measurement may be very different to the rest of the set, but it may be due to genuine biological variation not experimental error.

Typical statistical tests employed are T-tests (to compare the mean value across two groups) and Analysis of Variance (ANOVA) to compare multiple groups.

Fluxomics

A subset of targeted metabolomics is fluxomics (Winter and Krömer, 2013; Munger *et al.*, 2008), which seeks to determine the rates of metabolic reactions within the samples. This differs from targeted metabolomics which provide a snapshot of metabolite concentrations.

Fluxomics can be performed using ^{13}C or ^{15}N labelled precursors introduced to the biological system – these have the same chemical properties as the unlabelled counterpart but an increased mass. They can therefore be discriminated using a mass spectrometer. The progress of the label down metabolic pathways can be quantified – the appearance of ‘heavy’ downstream metabolites – and the metabolic flux estimated.

Untargeted Metabolomics

Untargeted metabolomics experiments seek to measure as many compounds/metabolites as possible within a sample – it is an untargeted approach which ‘casts the fishing net’ as widely as possible. Samples are most frequently analysed using LC–MS (although GC–MS can be used) with a high-resolution mass analyser scanning a wide mass range, e.g., 50–2000 Th.

Detected components are compared across sample sets to find differences and yield biologically-relevant information.

Experimental Considerations

The components detected will depend upon the LC(GC)-MS experiment performed. Electrospray ionisation will allow observation of a different set of ions than APCI. Positive polarity will show different compounds than negative polarity. Even the choice of separation method, and derivatisation method for GC, will change the panel of metabolites observed. It is important to remember there is no global ‘see everything’ metabolomics assay.

Biological replicates are very important here – the mean peak area obtained from compound X is compared between ‘test’ and ‘control’ sample sets to search for (significant) differences which may provide information about the biological state of the samples – an upregulation in a certain metabolic pathway for example. Sufficient replication to accurately describe the within-sample-set variation is therefore required.

It is also a good idea to include process blanks. Mass spectrometry is a very sensitive detection technique and will detect many background and contaminant ions from the solvents, solutions, plasticware etc used in the experiment – interfering signals not due to the sample. By including blanks in experiments and subsequent data analysis these ‘background components’ can be recognised and dealt with appropriately.

Workflow

Untargeted metabolomics experiments generally follow the same workflow, shown schematically in Fig. 8.

There are many software packages available to facilitate the analysis of untargeted metabolomics data.

Instrument manufacturers generally produce a commercially-available software to work with data from their own instruments. SIEVE and Compound Discoverer (ThermoFisher), ProfileAnalysis (Bruker), Progenesis QI (Waters) and MassHunter (Agilent) for example. Progenesis QI also will analyse data from other instrument manufacturers.

There are many freely-available tools available on the web, which are more universally-applicable. The most popular being XCMS(2) (Smith *et al.*, 2006; Gowda *et al.*, 2014), MetaboAnalyst (Xia *et al.*, 2009, 2015) and MzMine2 (Pluskal (2010)).

Fig. 8 Workflow of an untargeted metabolomics experiment.

MetabolomeExpress (Carroll *et al.*, 2010) is also used for GC-MS data analysis. Data generated from Data Independent Analysis (DIA) experiments can be analysed using MS-DIAL (Tsugawa *et al.*, 2015).

At the time of writing there is no universally recognised 'best' software or approach, usage depending on the experiment, user preference and software availability.

Data Pre-Processing

Data conversion

The output from the mass spectrometer is encoded in a format specific to the instrument manufacturer. These generally need to be converted into open source formats prior to software interrogation, particularly when using vendor-independent or freely available software both on- and off-line.

Widely usable data formats are NetCDF, mzDATA, mzXML and mzML. Instrument manufacturers frequently include an option to export data to this format from within their own data analysis software.

A useful data conversion tool is the open source ProteoWizard (Kessner *et al.*, 2008), this tool accepts data from a wide variety of instrument manufacturers and will batch convert into open source formats.

Data import

The first step in data analysis is to import the data into the metabolomics analysis software, this is normally performed in an automated manner. The 3-dimensional data sets (time vs m/z vs intensity) are then prepared for analysis. The data may contain an extra dimension – MS/MS – which is useful to aid in compound identification but is ignored during the early processing stages.

The three-dimensional data is generally converted into stacks of two-dimensional chromatograms by plotting the signal intensity of narrow m/z windows against time to produce extracted ion chromatograms. The size of these bins will depend on the mass analyser used – the data obtained from high resolution instruments allows many small bins to be used and therefore have high discriminating power between compounds of very similar molecular weight. The data from low resolution instruments can only be put into large windows or bins.

Data alignment

The data is then aligned – the instrument time required to analyse large numbers of samples can be significant, and variations during the data acquisition produce small shifts or drifts in chromatographic retention time. Signal from m/z X at time Y cannot therefore simply be compared across samples. There needs to be some alignment (shifting/warping) in the time dimension to line up the data and ensure correct comparison across samples and sample groups (Fig. 9). The shift is not a linear one and so warping algorithms are preferred. These are numerous (Smith *et al.*, 2013) and include Time Correlation Optimised Warping, Dynamic Time Warping and Parametric Time Warping (Tomasi *et al.*, 2004). There is no clear 'best' algorithm, with results being context and data dependent.

Missing values can be a significant problem for metabolomics statistical analysis – what is done when a signal is present in one sample set or one sample within a sample set but not the other(s)? Various approaches have been employed to solve this including missing value imputation (Armitage *et al.*, 2015; Hrydziusko and Viant, 2012; Di Guida *et al.*, 2016) or producing an aggregate run from all samples in the dataset and then using this for peak picking. This ensures the same ion is detected in every individual run and produces a complete data set which is required for valid multivariate analysis. Backfilling with zeros for missing values does not produce a valid dataset for multivariate analysis and should be avoided. However, there is no clear 'best' solution to the missing values problem, with results being context and data dependent.

Fig. 9 Cartoon example of unaligned and aligned LC-MS data.

Data normalisation

After alignment the data is then normalised (scaled) to adjust for experimental noise and variation. The goal is to remove experimental bias whilst keeping the signals relating to genuine biological differences (De Livera *et al.*, 2015). Examples of sample systematic bias include differences in sample concentration, particularly with biofluids – for example urine can be more dilute or more concentrated depending on the individual's hydration status. Experimental variations in signal due to sample preparation and instrumental analysis can also arise. Targeted metabolomic analysis can correct to a 'housekeeping' endogenous metabolite such as creatinine in urine, although this can be problematic due to the assumptions made. The ideal solution is the use of internal standards to correct for experimental bias, however a single internal standard will not correct properly for all the compounds detected in an untargeted experiment. The use of multiple internal standards improves the situation although this is still not ideal. Normalisation methods based on statistical methods (unit norm, median and quantile), scaling methods (auto scaling, range scaling, Pareto scaling, vast scaling and level scaling) and data transformation (log and power) are all employed (Sugimoto *et al.*, 2012). There is no consensus best approach, and several should be tested (Di Guida *et al.*, 2016).

Metabolite Detection

Peak picking and deconvolution

Peak picking algorithms are then applied to the aligned and normalised data to identify peaks over a user specified threshold, for example peak height or peak area. Wavelet transformation and Gaussian-curve fitting is commonly used to distinguish signal to noise (Smith *et al.*, 2006; Tautenhahn *et al.*, 2008), although manual tuning and checking is required due to the compound-specific variation in chromatographic peak shape, particularly with LC-MS and CE-MS. The output is generally a list of mass-retention time pairs e.g., *m/z* 100-4.5 min refers to a compound of *m/z* 100 which elutes with a peak intensity maximum at 4.5 min. Each of these will have an associated integrated peak area.

This data can then be deconvoluted or reduced – each compound may ionise in different ways or fall victim to fragmentation in the source region of the mass spectrometer. For example, a compound may be protonated, sodiated and be observed as protonated with loss of water $[M + H - H_2O]^+$. These can be recognised as they will have matching chromatographic profiles (signal vs time) and can then be deconvoluted to a single data entry of mass and retention time. Reducing the size of the dataset at this point simplifies the downstream data analysis. Caution must be applied however – these could be separate species which happen to have the same chromatographic profile.

Feature list

The final output of this process is a feature list or data matrix. The matrix contains the features detected and their abundance (integrated peak area) within the different samples.

Data can then be filtered – for example only those features showing a fold change greater than $2 \times$ between test and control or only those features observed with high significance or with a low coefficient of variation.

Exploratory data analysis methods are then used to find patterns in the filtered or unfiltered data

Statistical Data Analysis

Data analysis normally employs multivariate analysis (Worley and Powers, 2013). This is used to identify metabolite patterns that correlate in a statistically significant manner with a sample set/phenotype so that they can be used for diagnostics.

The main reason for using multivariate as compared to univariate analysis for metabolomics is simply since there are many variables in each sample, and these usually correlate to the phenotype in a concerted fashion rather than correlating independently. For example, your fingerprint contains many data points which combine to a unique whole. Consequently, it is important to identify metabolic profiles or 'fingerprints' that relate to the phenotype rather than individual, independent biomarkers.

It is important to apply appropriate statistical tools for the experiment. For example, comparing 'test' and 'control' samples can be done using one-factor ANOVA to search for statistically significant differences between groups. However, if the samples are a time course study with several samples being taken from the same source (for example a cell culture being sampled at 0, 4, 8, 24 h) then one-factor ANOVA is not appropriate as the groups being compared are not truly independent. In this case different tools such as repeated measures ANOVA must be employed.

Multivariate analysis tools can be supervised or unsupervised. Unsupervised methods are exploratory in nature, showing previously unknown patterns in the data (Fig. 10) or helping to confirm suspected patterns. Supervised methods use experimental knowledge (for example sample groups) to discover associated patterns.

Principal Component Analysis (PCA) (Jolliffe, 2002) is frequently used for untargeted metabolomics data analysis. This is an unsupervised data analysis tool – the algorithm is unaware of which are test, and which are control samples. PCA allows clustering of sample sets and to determine which variables (compounds/features) have the highest ability to discriminate between the sample sets.

PCA is an unbiased process and may reveal previously unknown clusters in the data – for example when comparing healthy vs diseased patients, we may see further splitting into groups male and female or fed and fasted. This can help to recognise limitations or errors in the experimental design.

Fig. 10 Cartoon Principal Component Analysis (PCA) Plot demonstrating clustering of 3 sample groups.

The clusters/groupings also allow recognition of samples which may be outliers – they do not cluster with the rest of their biological group.

However, PCA only reveals group structure when within-group variation is less than between-group variation and so may not provide separation between very similar samples.

Alternative tools employ Partial Least Squares algorithms to discriminate groups (Barker and Rayens, 2003). Partial Least Squares Discriminant Analysis (PLS-DA) and Orthogonal Partial Least Squares Discriminant Analysis (OPLS-DA) are the most well-known tools for multivariate analysis in metabolomics (Brereton and Lloyd, 2014). These are supervised analysis tools – information about which samples belong to which group is given to the algorithm. The algorithm then seeks to maximise the differences between the sample groups and show the variables responsible for this separation.

A danger of employing these algorithms is that they can aggressively over-fit models to the data, almost always managing to separate the defined groups or classes. Consequently, PLS-DA and OPLS-DA can generate excellent class separation from random data! This can be controlled for somewhat by creating training sets and testing them with other data or by performing permutation tests.

An alternative statistical tool is to use clustering methods on the data. These are unsupervised machine learning techniques which seek to group samples together using similarities in their measurements. Frequently used clustering techniques in metabolomics are K-Means (Hartigan and Wong, 1979), Hierarchical Clustering (Johnson, 1967), and Self-Organising Maps (Kohonen, 1990).

Further data analysis

Most metabolomics software packages will allow export of the data matrix (feature list) in .csv format. This file can then be further analysed in statistical packages such as the commercial SIMCA-P or the freely available R software using scripts.

Metabolite Identification

The final stage of data analysis is to identify those compounds (Kind *et al.*, 2017; Vaniya and Fiehn, 2015) found to be of likely biological interest – statistically different between groups and/or discriminating between groups for example.

Identification is not a trivial task, hence efforts are generally directed towards ‘interesting’ metabolites rather than trying to identify every feature identified in the experiment.

The information obtained about a compound will be molecular weight, retention time on the LC or GC and perhaps an MS/MS fingerprint. These properties can be targeted in database searches.

Several online and accessible chemical and metabolomic databases are available

- ChemSpider (Pence and, Williams, 2010) is a large chemical database, containing over 60 million structures from hundreds of data sources. It is the most complete and therefore the biggest chance of a ‘hit’. It is also the biggest chance of a false positive.
- PubChem (Wang *et al.*, 2009) is another large general chemical database provided by the NIH.
- Metlin (Smith *et al.*, 2005) is curated specifically for metabolomics experiments, containing MS and MS/MS spectra.
- Human Metabolome Database – HMDB (Wishart *et al.*, 2017), contains detailed information about metabolites found in the human body.
- Small Molecule Pathway Database – SMPDB (Jewison *et al.*, 2014) contains more than 700 small molecule pathways found in humans and can assist with pathway elucidation and discovery.

- Kyoto Encyclopaedia of Genes and Genomes – KEGG ([Kanehisa et al., 2017](#)) contains pathway information including genomes, proteomes and metabolomes from a variety of species.
- MassBank ([Horai et al., 2010](#)) is a large shared mass spectral data repository.

The largest database is not always the best – it will contain many species not related to the samples under analysis, therefore increasing the search space and complicating the analysis. A reasonable strategy would be to attempt identification using the smaller and better curated databases first, moving on to larger databases as required.

Identifying a compound by molecular weight alone is very difficult – imagine trying to identify a single person in a stadium full of people using only their weight. It is obvious that there will be many people/compounds of the same or similar (molecular) weight, and that discriminating these will be difficult. High resolution and accurate mass data is helpful here as it significantly narrows the search space. However, even measuring with sufficient accuracy to yield an elemental composition does not usually provide sufficient discrimination to narrow down to a single compound – isomeric or isobaric alternatives are possible.

Chromatographic retention time information can be helpful to narrow the search space, but is not frequently employed due to the wide variation in separation methods employed in different laboratories and consequent wide variation in experimental retention times obtained. An exception to this is the Golm Metabolome Database which contains GC–MS data and uses retention times scaled to a set of standards.

Further information within the mass spectrum can be useful – the relative intensities of the lower abundance isotopes of the compound to confirm isotopic composition for example – but are not often utilised.

Tandem mass spectra or MS/MS fingerprints are useful discriminatory tools but currently only a limited number exist in the available databases for LC–MS based metabolomics ([Vinaixa et al., 2016](#)). This is due to experimental variation in spectra obtained from different instrument configurations and different instrument manufacturers, which makes production of a library difficult. However, in the case of Electron Ionisation GC–MS the spectra obtained are very similar across different instruments and different manufacturers and hence a large generic GC–MS database is commercially-viable. The most commonly used of these are from Wiley and NIST. Employing these large spectral libraries makes confident identification of species observed in GC–MS currently much easier than LC–MS.

An increasingly popular alternative is to compare the experimental spectra with those obtained from rules based in silico fragmentation of a large library of molecules using software such as the commercial Mass Frontier, Progenesis QI, or the freely available MetFrag ([Ruttkies et al., 2016](#)).

Once a tentative identification has been made using database searching then experimental confirmation should be performed using a purchased or synthesised authentic standard. The standard should have the same behaviour – observed m/z , retention time and MS/MS fingerprint – as the unknown. It is preferable to perform large scale purification and NMR as a ‘gold standard’ confirmation. Standards are not always available, making this the only option in these cases.

Pathway Analysis

Metabolomics data can be employed as part of a systems biology approach looking to understand the interactions between genes, proteins and metabolites ([Krumsiek et al., 2016](#); [Johnson et al., 2016](#)).

This can be employed using various ‘pathway analysis’ tools. Some are incorporated into online metabolomics software such as XCMSOnline and MetPa within MetaboAnalyst. Others are commercially-available packages such as Ingenuity Pathway Analysis from Qiagen Bioinformatics.

The tools will input metabolite information – identity and concentration/peak area – and combine it with protein and gene data from different experiments. The combination allows a bigger overview and provides mechanistic insight – upregulated enzymes resulting in an increase of their metabolic output for example.

This valuable information comes at significant time and money cost – the input must be heavily curated, only including truly significant differences between sample groups. Often further experiments must be performed to confirm the identities of the metabolites observed.

Biological Interpretation

The final stage in metabolomics analysis is of course biological interpretation – making sense of the how the observed changes in metabolites map to changes in the phenotype. Having well-curated data at this stage is paramount. Interpretation can be somewhat of an iterative process – if unexpected changes are observed are we confident about the statistics and identity of this metabolite? If expected changes are not observed have we missed something by over filtering the data or misidentifying the metabolites?

Major Challenges in Mass Spectrometry-Based Metabolomics

Mass spectrometry powered metabolomics is a powerful tool, providing rich, reproducible and high-quality data from the samples analysed. It is not without shortcomings however, which can be broadly categorised into experimental and data analysis.

Experimental

- Control of samples – requirements for large numbers of well-controlled biological replicates.
- High cost of equipment.
- High level of expertise required to perform sample preparation reliably and reproducibly.
- High level of expertise required to operate mass spectrometers and obtain reliable, reproducible data.
- Importance of experimental design – the data obtained must be able to answer the questions asked.

Data analysis

- Variety of data formats produced from different instruments – often require conversion before analysis.
- Data quantity and large file sizes (up to several GB per sample) make data handling difficult and time consuming.
- Appropriate handling of outliers can be difficult to decide.
- Requires appropriate selection of data analysis tools, PCA vs PLS-DA for example.
- Difficult to identify metabolites from mass spectrometric data alone.
- Observation of a metabolite change between phenotypes does not mean that this metabolite is responsible for the phenotype – causality or coincidence cannot be established directly from the data.

Lack of standardisation of rigour, experimental approach, outputs and reporting between different labs and instrument manufacturers is currently a large problem in metabolomics (Rocca-Serra *et al.*, 2016). This makes comparisons and reproducing results between different laboratories very difficult. Also, for example, the data output format of the metabolomics experiments may not match the requirements for input for pathway analysis, depending on the software used. Consortia such as the Metabolomics Standards Initiative (Fiehn *et al.*, 2007) and COSMOS (Salek *et al.*, 2015) have been set up to tackle some of these issues. There is movement in the right direction, for example the adoption of International Chemical Identifiers (InChIKeys) to describe metabolite structure. The Metabolomics Workbench (Sud *et al.*, 2016) also offer a public repository for metabolomics data, helping standardisation and research efforts.

Applications

Targeted and untargeted metabolomics have an incredibly wide variety of applications. These include toxicology, study of disease, nutrition and functional genomics.

Future Directions

Metabolomics has a bright future and is an area of intensive research around the globe. Future areas for improvement include

- Advances in instrumentation such as more accurate and more sensitive mass spectrometers and more powerful separation technologies.
- Advances in community analysis such as widely-available cloud-based databases for compound identification.
- Increasing numbers of MS/MS libraries suitable for searching for identities within LC-MS/MS data.
- Community databases of ‘known unknowns’ where the metabolite’s identity could not be ascertained, but is observed by other laboratories in their samples.

Biographical Sketch

Doctor Russell Pickford was first introduced to metabolite mass spectrometry during his undergraduate degree in 1999 (Sheffield University). He then went on to study an MSc in Analytical Chemistry (Warwick University) and a PhD in biological mass spectrometry (University of Manchester and University of York). Following this he moved to the Bioanalytical Mass Spectrometry Facility at the University of New South Wales in 2003. He is responsible for the 'small molecule' mass spectrometric analysis team. He enjoys work on a wide range of projects including small molecule quantification and characterisation, metabolomics and lipidomics.

Metabolic Profiling

Nomenclature

^{13}C	Carbon-13	MHz	Megahertz
^1H	Hydrogen, proton	MS	Mass spectrometry
ANOVA	Analysis of variance	MS/MS	Tandem mass spectrometry
BMRB	Bio-magnetic resonance bank	MWAS	Metabolome-wide association study
COSY	Correlation spectroscopy	n	Number of samples
δ	Chemical shift	NMR	Nuclear magnetic resonance
DIMS	Direct-infusion mass spectrometry	OLS	Ordinary least squares
FDR	False discovery rate	OPLS	Orthogonal projections to latent structures
FID	Free induction decay	OSC	Orthogonal signal correction
FT-ICR-MS	Fourier-transform ion cyclotron resonance mass spectrometry	p	Number of variables (predictors)
GC-MS	Gas chromatography coupled mass spectrometry	PC	Principal component
GWAS	Genome-wide association study	PCA	Principal component analysis
HMBC	Hetero-nuclear multiple bond correlation	PLS	Partial least squares
HMDB	Human metabolome database	QqQ	Triple quadrupole mass analyzer
HSQC	Hetero-nuclear single quantum coherence	QTOF	Quadrupole time-of-flight
Hz	Hertz	RF	Radio frequency
ICA	Independent component analysis	STOCSY	Statistical total correlation spectroscopy
KEGG	Kyoto encyclopaedia of genes and genomes	TOCSY	Total correlation spectroscopy
LC-MS	Liquid chromatography coupled mass spectrometry	TOF	Time-of-flight
m/z	Mass-to-charge	TSP	Trimethylsilyl- $[\text{}^2\text{H}_4]$ -propionate
		X	Data matrix
		Y	Outcome variable

Introduction: Metabolic Profiling, Phenotyping and Fingerprinting

Metabolic profiling offers a powerful manner for providing a top-down systems level overview that captures the information from both genetic (host and microbiome – metagenome) and environmental (diet, environmental factors, exposures and lifestyle) origins. It involves measuring metabolites, small molecules that are typically under 1 kDa in molecular weight, in biofluids and other body samples (e.g., tissues, cells, breath) using spectroscopic or spectrometric methods to provide knowledge of the metabolic phenotype of an individual. The metabolic phenotype is the combined contribution of genetic and environmental impacts on the metabolic state under a particular set of conditions (Nicholson, 2006). The metabolic profile associated with a particular phenotype captures information that cannot be directly obtained from a genotype, gene expressions, epigenetic changes or the individual proteome, and in addition all these operate on different time scales adding to the complexity of drawing causal inferences from observed patterns (Nicholson and Lindon, 2008) – metabolic profiling aims to combat these problems by monitoring the global outcome and phenotypic traits of all these factors (environmental exposure, physiological status, system biochemistry) as a whole for utilization in personalized medicine (Holmes *et al.*, 2008b).

There are two main starting points of modern metabolic profiling using high-throughput spectroscopic (Nuclear Magnetic Resonance (NMR)) and spectrometric (mass spectrometry (MS)) techniques. The first is ‘metabonomics’ (Nicholson *et al.*, 1999) which is the analysis of the time-related, global, dynamic metabolic response in living systems to biological stimuli – it was exemplified using NMR spectroscopy and pattern recognition methods and focussed on finding the metabolites that are different between for instance disease states using multivariate statistical analysis for the first time in 1999. The second is ‘metabolomics’ (Fiehn, 2002) which was described in 2002 as the quantification, characterization and identification of the global metabolic profile in living systems – this initially focussed on using MS to identify as many metabolites in a sample. Over the years, these initial terms have been used interchangeably for studies using MS and/or NMR, with/without multivariate statistical methods and targeted or untargeted approaches. In the same way, as time passed, many different terms were introduced for these types of analyses such as metabolic fingerprinting, metabolic foot-printing, metabolic profiling and metabolite target analysis, for example, see review in Ellis *et al.* (2007), each aimed at a specific type of analysis of the metabolites with overlap in use of these terms by researchers. The first mentions of metabolic profiling in literature date back to the 1970s, way before the current time of high-throughput analysis that characterizes the current use of the term.

A metabolic profile is the result from a chain of conditional probabilistic interactions between metabolites themselves and with other components of the biochemical network, including gene-environment interactions amongst which bacteria, fungi, yeasts, archaea, viruses and parasites (Hooper *et al.*, 2012; Nicholson *et al.*, 2012a). Specific changes in metabolic flow that are out of the systemic homeostatic control can be mapped to pathway perturbations to connect with disparate biological events that operate on different time scales and in different compartments to provide a deeper understanding of the multi-layered perturbations and disruptions in disease development and therapeutic interventions. Metabolites that are shown to be associated with a type of physiological status, both reproducibly and quantitatively, can be used as potential biomarkers for disease diagnosis, therapeutic targets or for monitoring of treatment efficacy.

Backgrounds and Fundamentals of Metabolic Profiling

Analytical Workhorses

Metabolic profiling relies on two main platforms that combine the gathering of systemic information from non- or minimally-invasive sampling of biological samples, for instance biological fluids such as blood/plasma/serum and urine, with high-throughput technologies capable to analyse thousands of samples. Both techniques have their advantages and disadvantages for the detection of metabolites, but because the biologically interesting molecules have different physicochemical properties the methods are complementary as no single platform is able to measure all metabolites in a biological sample (Bouatra *et al.*, 2013).

Nuclear magnetic resonance (NMR) spectroscopy

Metabonomics was exemplified using ^1H NMR spectroscopy in the first instance (Nicholson *et al.*, 1999). NMR spectroscopy measures specific quantum mechanical properties of the nuclei from atoms with an odd number of (protons + neutrons). The simplest example of an atom that has an intrinsic angular momentum, and thus non-zero spin, is hydrogen (^1H) which only has a single proton in the nucleus. The quantum mechanical spin can either be up or down and it is this property that is used to analyse molecules with NMR spectroscopy.

A very strong magnetic field (in MHz) forces all quantum mechanical spins of nuclei to align either parallel to the field ("spin up," lower energy state) or anti-parallel ("spin down," higher energy state). After which a broad range of radio frequency (RF) pulses are used to excite all protons and bring them in a higher energy state perpendicular to the magnetic field (90° pulse), the difference in energy between states is dependent on the magnetic field strength and on the molecule the proton is attached to, as electrons shield protons slightly from applied magnetic fields. Immediately after the pulse stops, all spins are perpendicular to the magnetic field in a higher energy state and they go back to the lower energy, or relaxation, states (aligned with the field) and they emit the absorbed radiation which induces a current in a coil that is wrapped around the sample tube. The signal, known as the free induction decay (FID), contains all the different observed frequencies in the time domain with the difference in frequencies (in Hz) known as the 'chemical shift.' In order to obtain a frequency domain NMR spectrum the FID is Fourier transformed and this results in a spectrum of peaks, the average over multiple FIDs is used to improve the signal-to-noise ratio.

Comparison of spectra in metabolic profiling is made possible by optimized pulse sequences and by the addition of an internal standard which usually is the sodium salt of trimethylsilyl- $[\text{}^2\text{H}_4]$ -propionate (TSP) in aqueous (biofluid) media (Beckonert *et al.*, 2007). The nine protons of TSP are magnetically equivalent and are maximally shielded because the carbon atoms they are attached to are attached to the most electronegative atom, silicon. This means the emitted energy of TSP is highest and therefore it is used as reference at a chemical shift (δ) of 0. To standardize over different magnetic field strengths, the δ of each signal is expressed as parts per million (ppm) – Hz per MHz.

A number of other properties can be used to differentiate different molecules from each other. First, the integral of different peaks from the same molecule are directly proportional to the number of protons. Second, nuclei have a small magnetic moment which influences the signals observed from other nuclei in the vicinity. This is called spin-spin coupling and causes the splitting of NMR peaks in specific patterns, also known as the multiplicity of a peak, and the relative intensities of the peaks in the multiplet follow Pascal's triangle. The most important of the coupling types is scalar coupling, which is the interaction of two nuclei through at most 3 chemical bonds. In a sample there are many molecules of the same compound of which the protons emit different energies when excited due to the different arrangements (up/down) of the spins. The fine structure of peaks from each metabolite is different and this is used to structurally identify metabolites. Most biological molecules have a carbon backbone, thus it is the CH bonds that are typically observed. NH and OH signals can still be observed; however they give weaker signals and are less shielded.

The advantage of NMR spectroscopy is that it requires relatively little sample preparation (Beckonert *et al.*, 2007; Dona *et al.*, 2014), the sample is not destroyed in the process of analysing it, analysis takes only a few minutes and a spectrum contains information about the structure of molecules. This makes NMR spectroscopy a good method for the high-throughput analysis of biofluid samples (Dona *et al.*, 2014) and a very reproducible method. The downside is that because many CH signals will have a similar 'molecular environment' the observed peaks/peak patterns can overlap which makes it difficult to distinguish between peaks from the same metabolite, in addition NMR spectroscopy is typically less sensitive compared to mass spectrometry.

Two-dimensional NMR spectroscopy techniques can be used for metabolite identification to uncover molecular interactions between nuclei. 2D J-resolved NMR spectroscopy separates homonuclear J-couplings along an orthogonal dimension from the

standard axis where both the chemical shifts and J-couplings appear. This has the benefit of reducing the overlap between peaks in an NMR spectrum. Other 2D experiments include the COReLation SpectroscopY (COSY) experiment, which measures correlations between nuclei separated by at most 3 chemical bonds, to study neighbouring atoms and TOverlaid Correlation SpectroscopY (TOCSY) which does the same but over longer distances to create 2D $^1\text{H} - ^1\text{H}$ spectra. Hetero-nuclear 2D experiments do the same but for $^1\text{H} - ^{13}\text{C}$ in the Hetero-nuclear Single Quantum Coherence (HSQC) spectroscopy (one bond) and Hetero-nuclear Multiple Bond Correlation (HMBC) spectroscopy (more than one bond). With the exception of J-resolved spectroscopy, ^2D NMR experiments currently take too much time to be used for profiling studies and are therefore solely used for metabolite identification purposes.

Mass Spectrometry (MS)

The description of metabolomics in 2002 (Fiehn, 2002) focussed heavily on MS approaches, including gas chromatography prefaced MS (GC-MS), liquid chromatography prefaced MS (LC-MS) and Fourier-transform ion cyclotron resonance MS (FT-ICR-MS), but also considered NMR spectroscopy. The concept of mass spectrometry is to measure the mass of a compound that is ionized, expressed as a mass-to-charge (m/z) ratio, and can determine the elemental composition and isotopic signature of a molecule. For detecting the m/z ratios there are two main types of detectors used in metabolic profiling, most discovery based research is done using time-of-flight (TOF) detectors and for analyses requiring higher mass accuracies different types of 'ion traps' are used.

For TOF detectors ions are accelerated by an electric field of a specified strength so that each identically charged ion has the same kinetic energy. Ions with large m/z ratios have lower velocities than lower m/z do, therefore the time it takes for an ion to reach the detector (typically an electron multiplier tube) is directly proportional to the m/z ratio. Quadrupole mass analyzers use four parallel metal rods of which the opposing rods are connected electrically. An RF voltage is applied between the pairs resulting in ions with small m/z ranges being able to pass through the quadrupole, whereas others will collide with the rods. This allows specific m/z to pass through and reach the detector based on the variable voltage. Quadrupoles can be followed by an electron multiplier tube detector alone or precede a TOF detector (QTOF).

The second type of detectors are ion traps and they come in many different forms; the main ones used in metabolic profiling are triple quadrupole mass analyzers (QqQ) where the second quadrupole serves as a collision cell for fragmentation of ions, FT-ICR ion traps and Orbitraps. QqQ's work the same as a normal quadrupole, however now the third quadrupole now selects the fragmented ions (from the second quadrupole) to reach the detector – this often used as method for identification of specific molecules based on their fragmentation patterns and is called tandem-MS or MS/MS. FT-ICR and Orbitraps work based on the concept of having ions go in orbit around a central point and measuring the image current generated by the orbiting ions. In FT-ICR this is achieved by using a magnetic field to force the ions to spiral and in an orbitrap ions are orbiting around a central electrode in a spiral due to electrostatic forces. The different frequencies of the image currents depend on the oscillations of ions of different m/z ratios. Fourier transforming the image current results in a mass spectrum. Different methods exist to perform tandem-MS experiments in FT-ICR and Orbitraps.

It is important to realize is that all these detectors require the molecules to be in the gas phase. In metabolic profiling aqueous samples are usually ionized using electrospray ionization, which disperses the sample to create an aerosol and applies high voltage to create either positively charged ions ("positive mode"), usually by the addition of a cation (H or Na), or negative ions ("negative mode") by loss of a hydrogen.

MS has the advantage over ^1H NMR in that it can provide information of the mass of a compound that can be used to identify a compound. Measuring all masses simultaneously in mass spectrometry can be done using direct-infusion MS (DIMS) and a spectrum can be obtained within minutes (Draper *et al.*, 2013) which makes it a good method for high-throughput analysis of biofluid samples.

However, it has some disadvantages such as reduced ionization efficiency due to the simultaneous ionization of all compounds in the sample, which may contain less volatile compounds, and the corresponding co-elution of metabolites into the mass detector (Draper *et al.*, 2013), the inability to distinguish between molecules with molecular masses that fall into the same mass-to-charge (m/z) bin and batch differences due to changed experimental conditions (Kirwan *et al.*, 2013). The former two of the disadvantages can be solved using a separation technique before ionization, such as LC, GC or capillary electrophoresis to separate compounds based on physicochemical properties. The separation step improves the identification of compounds not only because less metabolites co-elute, but also because additional information is available from the separation set (retention time) that can be used to identify metabolites based on physicochemical properties in addition to the m/z -ratio (see Fig. 1).

However, these 'hyphenated' techniques also have disadvantages, for example, the increased run-time makes high-throughput experiments less feasible, the conditions of the chromatographic separation step can change when analysing many samples which then makes the identification of important metabolites more difficult and also metabolites may ionize favourably in either positive or negative mode, therefore experiments would have to be done using both modes of ionization. Dedicated data processing packages, such as XCMS (Smith *et al.*, 2006), focus on retention time alignment, and peak detection, filtering and matching, between spectra. Recent advancements in sample preparation, automated measurements and methodologies for MS-based metabolic profiling are improving its reproducibility for the analysis of large data sets (Want *et al.*, 2010; Dunn *et al.*, 2011). Specific assays and libraries exist for different applications, such as those specifically tailored to the analysis of lipids (Fahy *et al.*, 2009; Kind *et al.*, 2013), and online platforms for data processing (Tautenhahn *et al.*, 2012b).

Fig. 1 Example of LC-MS global metabolic profiling analysis of a human urine sample in positive ionization mode. (A) Baseline corrected chromatogram with the ten most intense peaks labelled by their retention time and one selected peak highlighted in blue. (B) Zoom of the selected peak. (C) Mass spectrum extracted from the selected peak, the ten most intense masses are labelled by their m/z ratio. (D) Zoom of the most intense peak in the mass spectrum shows the isotope pattern for a compound with likely elemental composition $C_{15}H_{28}NO_4$.

Statistical Methods

The high-throughput analysis of samples using NMR spectroscopy and MS yields data (X) with many thousands of variables, thus for data analysis this results in data sets where the number of variables far exceeds the number of samples ($n < p$). This is problematic in standard regression methods, such as ordinary least squares (OLS), because variables will no longer be linearly independent and thus $X^T X$ might become (close to) singular and non-invertible. In metabolic profiling different methods are used to deal with the multivariate nature of the data and deal with collinearity of variables to find models that are able to predict samples well and simultaneously provide a metric of assessing the relative contribution of each variable in the predictive model.

Dimension reduction techniques

One approach used in metabolic profiling is to reduce the dimension of the data by decomposing the data into multiple orthogonal linear combinations of the original variables. Principal Component Analysis (PCA) (Hotelling, 1933), also known as Singular Value Decomposition (SVD), is used to decompose X into three parts: left singular vectors (U), a diagonal matrix with singular values (Σ) and right singular vectors (V), where the original data can be reconstructed using these three matrices using $X = U(\Sigma)V^T$ —PCA is a form of a linear-mixture model. The PC scores ($T = U(\Sigma)$) are used to look for differences between groups of samples in specific PCs by using the scores as a new coordinate system. The sum of the squared elements on the diagonal of (Σ) is equal to the total variance of X and indicates the relative importance of each component. V is used to pinpoint the variables responsible for separation by looking at the magnitude of a variable in a PC that gives information about the weight of a variable ('loading') on the transformation of a spectrum into a score. PCA is often used to 'get a feel' for the data, to see if unsupervised decomposition into latent variables based on the variance can show some signs of clustering according to the experimental design. The benefit of PCA is that components are ranked based on how much variance of X they describe, which can be used as a proxy for their importance.

However, in modern metabolic profiling PCA is rarely sufficient on its own to show differences between groups. Many different processes might impact the concentration of metabolites that may not be easily captured by linear methods. Decomposition of data in specific components according to experimental design can be performed in a supervised manner using ANOVA-based decomposition of the data into effect (data that co-varies with experimental design) and residual (data whose variation is unique and unrelated to experimental design) matrices before analysis of both of these matrices, or only the effect matrices, by PCA (Zwanenburg *et al.*, 2011).

A related approach to PCA is Independent Component Analysis (ICA) which can be used to capture non-linear, and non-Gaussian, metabolic processes from the data. It does so by decomposing X into a mixing (A) and a separating matrix (W), where A gives information about the contribution of samples in each independent component and W indicates the relative importance of variables in each component (Hyvarinen and Oja, 2000). The benefit of ICA is that it aims to find non-Gaussian, thus potentially informative, latent variables and that these are orthogonal to each other as with PCA, a related technique to ICA called Projection

Pursuit does not have the orthogonality constraint. One potential disadvantage of ICA is that it is not straightforward to assess *a priori* how many independent components are required, however the variance explained by k ICs is the same as for the first k PCs. Therefore similar methods can be used as with PCA to determine this for instance to select a cut-off for the eigenvalues or the percentage of variance of X explained by the components.

Classification algorithms

High variance is not necessarily equivalent to high information content. Therefore most metabolic profiling studies make use of supervised methods that aim to identify linear combinations of variables that co-vary with an outcome vector or response variable (Y). The most commonly used methods in metabolic profiling for multivariate regression and discriminant analysis are Partial Least Squares (PLS) (Wold, 1973) and its extension Orthogonal Projections to Latent Structures (OPLS) (Trygg and Wold, 2002).

PLS can be seen as an as a supervised extension of PCA, in that it seeks direction in the data with highest (co-)variance with the response variable, like PCA it calculates multiple orthogonal components. However, unlike PCA – or SVD specifically – these components cannot be obtained in a single step, but are found using a sequential procedure. The weights of the first PLS component are found based on the decomposition of $X^T Y$, and the first score vector is found by multiplying X with the weights, $t = Xw = X(X^T Y)$ – for a univariate Y , decomposition of $X^T Y$ is $X^T Y$ itself. The corresponding loading vector is found by multiplying X^T with normalized scores, $p = \frac{X^T t}{t^T t}$. The residual, or ‘deflated,’ X is found by subtracting tp^T from X . The same process, finding the corresponding loading and finding the residual, is performed for Y . Sequential components are obtained from the residual X and Y using the same process.

The popularity of PLS in metabolic profiling can be explained by the simple linear algebraic nature of PLS, and the low computational costs associated with it. Optimizing the number of components is performed by minimizing the cross-validation error. Including more components will improve the prediction of the model (training) set, but comes at a cost of over-fitting and possibly sub-optimal prediction of the validation (test) set. In order to assess a model’s predictive ability a second validation set must be set aside prior to data analysis to avoid biased results, this can be incorporated into a double cross-validation framework (Filzmoser *et al.*, 2009). In addition, to avoid reliance on a single model, some recent metabolic profiling studies have used Monte Carlo double cross-validation which has an important benefit in terms of providing a means of assessing variable importance (Garcia-Perez *et al.*, 2017).

Traditionally, the assessment of important variables in PLS models in metabolic profiling are based on either (a visual inspection of) the magnitude of variables in the loadings, the magnitude of the regression coefficients (by combining multiple loadings into a single regression coefficient vector), calculating the correlation between the predicted scores and the original data, or to assess the importance of a variable in terms of magnitude of each component weighted by the contribution to the model of that component (variable importance on projection) (Mehmood *et al.*, 2012). The difficulty lies in the fact that all variables contribute in a PLS model, i.e., the coefficients are all non-zero – unlike coefficients in penalized regression techniques such as the lasso and elastic net. Some approaches can borrow from univariate statistics and multiple testing corrections. For example, calculating the correlation between the predicted scores and the original data will give information about which variables are likely to be associated with the predicted scores. Despite the fact that the scores come from a multivariate model, calculating correlations of it with all original variables has the potential to give false positive associations with the predicted outcome and as well with the true outcome. A simple form of multiple testing correction on the P -values associated with each of the correlations can limit the number of false positives for correlations with predicted scores. However, outliers in the predicted scores, or even a bad predictive model, can still give rise to ‘significant’ correlations. Therefore these correlations may not explain the true outcome, as the predicted scores are used as proxy for the true outcome. In addition, reliance on a single model may not generalize well. From all individual models from a Monte Carlo model the mean regression coefficient can be used as a more robust estimate of the true coefficients. Dividing the regression coefficient by its variance can give a t -score which can be converted into a P -value and adjusted for multiple testing. Estimating the mean and variance from the same models can give biased results. Garcia-Perez *et al.* (2017) therefore opted to include a number of bootstrap resamplings of each individual model to obtain an unbiased estimate of the variance of regression coefficients in a Monte Carlo model.

The methods to determine variable importance above are all filtering methods, in that they are calculated *a posteriori*. If a subset of variables is deemed important enough, a new sparser model using only those variables can be calculated, however, it will need to account for the fact that all data that has been used are now biased. Therefore, this requires a third independent validation set that has been completely set aside from the get go to inform on the predictive ability of the new model. Most metabolic profiling studies are not set up for this to be possible.

OPLS is an extension of PLS where data is separated into variation orthogonal to Y and non-orthogonal (informative for outcome) to Y . Two main methods are used that use Orthogonal Signal Correction (OSC) (Eriksson *et al.*, 2000) to extract orthogonal variation. The first is to adjust the data matrix by removing variation from X that is orthogonal to Y . The first score from PCA is used and orthogonalized to Y , once stable the corresponding loading of the orthogonal score is calculated as the loading in PLS is calculated, and this variation is removed from X . This process can be repeated as much as deemed necessary (based on cross-validation). This process of removing non-orthogonal variation from X allows more variation non-orthogonal to Y to be captured in the first few PLS components. Analysis is carried out using regular PLS on the OSC corrected X matrix, X_{OSC} . The second method is to find the first component using PLS and adjust this *a posteriori* for non-orthogonal variation. Often the first predictive and first orthogonal components are used to visualize the class separation in a two dimensional score plot for this method.

Molecular epidemiology

Molecular epidemiology data is characterized by a wealth of metadata in addition to metabolic profiling data. Data analysis focusses on correcting for possible confounding effects that can be identified or gathered from the metadata. Typically this is done using univariate regression including possible confounding factors into a model with one variable at a time. The regression coefficients from all variables are converted to *P*-values and these are adjusted for multiple testing. Recently, these corrections have moved away from controlling the Family-Wise Error Rate, by for instance a Bonferroni correction, toward False Discovery Rates (FDRs) as some FDR methods are able to account for correlation between variables, whereas the Bonferroni correction assumes independent variables which for $n < p$ does not hold and in addition metabolites are intrinsically correlated. The Benjamini-Hochberg (1995) FDR and the *q*-value method (Storey and Tibshirani, 2003) are most commonly used, but owing to dedicated software packages (Strimmer, 2008) other methods able to deal with correlated data are now commonly used.

Bottlenecks in Metabolic Profiling

Following data analysis, important variables need to be identified in order to study them in relation to perturbations in the biological system under study. Metabolite identification is simultaneously one of the key aspects as well as a major bottleneck of metabolic profiling for both NMR spectroscopy and MS, as without it the interpretation of results is not-feasible (Wishart, 2011). Both statistical and bioinformatic, and analytical approaches are used complementarily for NMR spectroscopy and MS (Posma *et al.*, 2017).

Due to the accurate determination of the molecular mass of a metabolite, a chemical formula can be deduced from an MS experiment and both the mass and formula can be used to search in databases for chemical compounds with matching masses or formulae. A number of databases are dedicated to MS data specifically, such as METLIN (Tautenhahn *et al.*, 2012a) and MassBank (Horai *et al.*, 2010), to specific classes of compounds such as lipids, such as LIPID MAPS (Fahy *et al.*, 2009) and LipidBlast (Kind *et al.*, 2013), or tailored to specific platforms such as GC-MS and the FiehnLib (Kind *et al.*, 2009). Some of these databases include species that have not been formally identified or measured, for instance by including all possible combinations of di- and tripeptides in METLIN or inclusion of putative lipids in LIPID MAPS. MS/MS fragmentation patterns of compounds are often also included and searchable in the databases. Other databases focus on data from multiple sources other than MS, with the most widely used resource being the Human Metabolome DataBase (HMDB) (Wishart *et al.*, 2013). HMDB includes background information gathered from different sources and MS and NMR spectra of authentic chemical standards. PubChem (Kim *et al.*, 2016) and ChEBI (Hastings *et al.*, 2016) are the most widely used chemically annotated and curated chemical databases that can be used to find chemical structures and cross-reference with other databases, the Kyoto Encyclopedia of Genes and Genomes (KEGG) (Kanehisa and Goto, 2000) also contains information on the mass and structure of metabolites and links metabolites via chemical reactions and maps them in biochemical pathways. HMDB, as mentioned, contains a huge collection of NMR spectra, including 2D spectra, of authentic chemical standards. The Bio-Magnetic Resonance Bank (BMRB) (Markley *et al.*, 2008) is another online resource that contains many 1D and 2D NMR spectra of biologically relevant compounds, as well as MS spectra.

The benefit of NMR spectroscopy is that multiple peaks in a spectrum can belong to one and the same metabolite, their chemical shifts and multiplicities can give more information about the chemical structure. The fact that peaks from the same metabolite always appear in the same ratio to one another can be exploited in NMR metabolic profiling by calculating the correlation between one variable and all other variables in the data set, this has been dubbed statistical TOCSY (STOCSY) (Cloarec *et al.*, 2005) and has been one of major workhorses in metabolite identification for NMR metabolic profiling to identify the peaks with high correlations to a 'driver' peak as these are likely from the same metabolite. Different extensions have been proposed that improve on certain aspects, such as to use subset selection and multiple testing to improve the information recovery (Posma *et al.*, 2012), as well as methods to extract metabolite-metabolite interactions from the data and calculate cross-platform correlations (Robinette *et al.*, 2013). Once multiple peaks have been found to be associated with each other, these combinations of chemical shifts and multiplicities can be searched in databases such as HMDB and BMRB to find a match with known compounds and spectra (see Fig. 2).

However, not always do databases give an exact match, they might give no (exact) matches or a whole ranges of possible compounds. For the former, the only option is to perform additional experiments using 2D NMR and/or MS/MS to uncover more and complementary information about an unknown metabolite (Posma *et al.*, 2017). For the latter, experiments can be done by spiking in chemical standards to find a match, or more recently a new approach has emerged that uses metabolic network information, for example, from KEGG, to predict which match has the highest probability of being true based on a joint statistical model with other compounds that have already been identified in the sample (Cai *et al.*, 2017). This uses both the data and prior biological knowledge to narrow down the number of compounds that can be matched to a specific peak. Once a match has been found, it is confirmed using spike-ins with increased concentrations of an authentic chemical standard in a sample which are re-run using the same experiment and experimental conditions to confirm the identity.

Databases rely on the quality of the data provided to them, and in recent years a number of consortia have focussed on harmonising research in metabolic profiling, including analysis protocols, data processing, data analysis, annotation and data storage. This allows for research and data to be more effectively shared within the research community when specific reporting

Fig. 2 Example of ^1H NMR spectroscopy metabolic profiling of a human urine sample. (A) Unprocessed 600 MHz ^1H NMR spectrum, including the internal standard TSP at δ 0 and water resonance at δ 4.74. (B) and (C) Zooms of two regions showing the splitting patterns (multiplicity) of peaks along the chemical shift axis. (D) Statistical spectroscopy analysis using STORM for metabolite identification (of δ 7.83) on a data set with 1208 urine samples shows correlation and covariance between variables, adjusted for multiple testing (p_{FDR} at 1%) and after subset selection ($n=1152$). Top bar is a 1D projection of the correlations and highly correlated variables belong to the same metabolite. (E) and (F) Zooms of two regions containing peaks from hippuric acid.

guidelines are followed. One example is the 'Coordination Of Standards in MetabOmicS' (COSMOS) (Salek *et al.*, 2015) which proposes to use specific data formats that allow simple linkage between data and metadata to facilitate improved data curation and uses the already existing and dedicated repository for metabolic profiling data MetaboLights (Haug *et al.*, 2013). More research focus has to go into automated annotation and (statistical) identification of metabolites in large data sets as these are cost-effective methods when compared to wet-lab chemistry methods that can narrow down the actual experiments that need to be performed for metabolite identification and biomarker profile validation.

Another challenge in metabolic profiling pertains to the analysis of datasets with $n < p$ and pinpointing important variables, as well as the often overlooked aspect of data processing. For instance in MS it is important to filter out noise peaks from the data prior to data analysis. One approach is to filter variables based on the number of non-zero values, i.e., measurements higher than the limit of detection. This procedure is prone to introducing bias into a model when class information is used for filtering, for instance to only select variables that are present in all samples from at least one class. Ideally the filtering step is included in the data analysis, where any noise variables do not contribute to the model. However, when methods are used for which all variables have non-zero coefficients this does not hold. Random Forests and other recursive partitioning methods are able to deal with huge numbers of variables, at relatively low computational cost, and simultaneously perform variable selection and are ideally suited for the analysis of high-dimensional MS data (Enot *et al.*, 2008). However, for NMR these methods are not ideal because of the correlated nature of NMR data, each metabolite can have multiple peaks which each have multiple data points (variables). Likewise, penalized regression methods such as the Lasso will not pinpoint all important variables, whereas the Elastic Net (Zou and Hastie, 2005) could do this, however optimizing the mixing and penalty parameters over a whole range of possible values comes at a heavy computational cost. This opens up the gap for methods, and specifically dedicated software packages, that simultaneously are able to deal with multi-collinearity, perform variable selection including

filtering out noise and are able to deal with large numbers of variables that can be used for MS- and NMR-based metabolic profiling alike.

Different Approaches in Experimental and Statistical Design

Some approaches focus on ‘global metabolic profiling’ in that they assay as many metabolites as possible, whereas others perform targeting of specific metabolites. While targeting can be more accurate experimentally, as the assay can be tailored to the measurement of a number of compounds, the resulting statistical model may be limited in the information it provides of the biological system for exactly this reason. Performing a global profiling analysis first and uncovering important metabolites which are then as a second step targeted for inclusion in a more sparse model, is potentially less biased than starting out using targeted methodology from the get go, and will provide a full(er) systems view.

Another major difference between studies is the statistical analysis of the data, specifically whether a univariate or multivariate approach is chosen. From a statistical point of view, there is no single right (or wrong) way to go about the analysis. From a more conceptual point of view, multivariate analysis make more sense considering the metabolites interact in a metabolic network themselves and can thus influence changes in disparate metabolic compartments. The most important aspect is that the results are properly validated, tested and that models are free of any bias.

Illustrative Examples of Metabolic Profiling

Metabolome-Wide Association Studies (MWAS) (Holmes *et al.*, 2008a; Elliott *et al.*, 2015) are used to find links between epidemiological and metabolic data, analogous to Genome-Wide Associations Studies (GWAS), that are collected at the same time to make inferences about the connections between disease risk factors and phenotype variation. The first study of its kind (Holmes *et al.*, 2008a) showed specific changes in the metabolic profile related to dietary, genetic, gut microbial co-metabolic and xenometabolic factors in relation to blood pressure in four different populations which provided testable hypotheses and important starting points for further research, such as investigating some blood pressure biomarker metabolites in relation to renal ion balance and possible kidney stone formation (Garcia-Perez *et al.*, 2012). The second study (Elliott *et al.*, 2015) focussed on the global profiling of urine and the relation to adiposity as a first stage using univariate statistics and multiple testing correction, and as a second stage specific additional metabolites were targeted, based on other targeted studies performed in other biofluids (Newgard *et al.*, 2009), and modelled in a penalized regression model (Elastic Net) to predict Body Mass Index. This was done on a reduced list of variables to alleviate the computational cost. The model was validated using an additional set of data of the same individuals obtained at a later time and tested in another population. The benefit of using a global profiling approach opposed to a targeted one was demonstrated by the fact that multiple areas known to be associated with obesity were all found simultaneously, such as muscle turnover, diet, amino acids and gut microbial metabolism, whereas targeted studies only identified bits and pieces.

Metabolic profiling can be used to provide information about disease aetiology, diagnosis or progression, for instance for prostate cancer progression (Sreekumar *et al.*, 2009), development of diabetes (Wang *et al.*, 2011) and prediction of survival from sepsis (Langley *et al.*, 2013). For prostate cancer it is important to have non-invasive measures of tracking progression, Sreekumar *et al.* found that one metabolite detectable in urine could be used to indicate progression and further experiments showed that knock-out of enzymes involved with sarcosine synthesis and degradation showed attenuation and increases of cancer invasion, respectively. Likewise, for diabetes and sepsis it was shown that a panel of metabolites in blood could be used to predict future diabetes and survival in sepsis patients.

Then there are the examples that highlight the capabilities of metabolic profiling to be used for personalized medicine, nutrition and care, for instance to predict drug effects (Clayton *et al.*, 2009), detect tumour margin status during surgery *in vestigio* (Balog *et al.*, 2013) and to assess adherence to dietary advice without relying on biased patient reports/records (Garcia-Perez *et al.*, 2017). Pharmacogenomics aims to stratify patients in specific groups that benefit from specific (drug) treatments, however the downside is that it does not capture the environmental variation, pharmacometabonomics aims to predict post-dose response to a drug or treatment based on pre-dose metabolic profile (Everett, 2015). For instance, paracetamol (acetaminophen) was shown to be metabolized differently, in the glucuronide rather than the sulfate form, by individuals based on the excretion of 4-cresylsulfate in urine (Clayton *et al.*, 2009) and, in addition, this observation highlighted the contribution of the gut microbiota that cannot be captured by other approaches such as pharmacogenomics. The second example details the potential of metabolic profiling to be used for the instantaneous detection of cancer tissue based on the metabolic profile of lipids in tissue. In cancer surgery it is imperative that no cancer tissue is left behind after a surgery and at the same time that as little healthy tissue is removed as possible. It is well known that cancer and healthy tissue, as well as different cancer types are characterized by different lipid profiles. The demonstration of the intelligent knife, mass spectrometry coupled to electrosurgery tools to analyse the biochemical composition of smoke after cutting tissue, has shown that on-line metabolic profiling using statistical modelling can match histopathology diagnosis of tissues perfectly and at the same time provide information on tumour biochemistry (Balog *et al.*, 2013). Finally there is public health nutrition which suffers from misreporting that confounds associations between diet and health. Metabolic profiling of urine was used to show that adherence to different diets could be assessed from the urine profile and that the metabolic profile from free-living individuals could be matched to different diets from a controlled clinical trial (Garcia-Perez *et al.*, 2017).

Discussion

Global metabolic profiling allows for an unbiased assessment of metabolites in a sample and can reveal novel and possibly unexpected perturbations in a biological system. The bottleneck point is the identification of metabolites that are deemed most important in a particular model. Specifically those that are considered ‘unknown unknowns,’ for instance compounds for which no match is found in any database or for which multiple matches remain, even after further structure elucidation using MS/MS and/or 2D NMR experiments. Identifying a compound that does not appear in any database and for which no authentic chemical standard is available is a tedious and cumbersome process requiring many different experiments (Posma *et al.*, 2017). Therefore most metabolic profiling studies focus on identifying unknowns that can be found using information in databases and validated using authentic chemical standards. Similarly, targeted profiling focuses on measurement of predefined groups of metabolites and thus may only provide a limited view. Combining a global profiling as a first stage and targeted analysis as second stage is a more powerful approach in which biomarker metabolites can be validated.

Most NMR-based metabolic profiling studies focus on global profiling, as all metabolites are measured in the same sample simultaneously. Hyphenated MS-based approaches have the benefit that they can be used both to target specific molecules based on retention-time and m/z , as well as to do global profiling. The benefit of NMR is that the sample is not destroyed in the process, which is beneficial when additional experiments are performed on the same sample for identification. Whereas MS is more sensitive than NMR which allows for more metabolites, specifically those present in low concentrations, to be profiled in a single analysis. In addition NMR can be used to analyse tissue samples in a similar way as biofluid samples are, whereas for MS this requires different techniques such as evaporative ionization MS techniques (Balog *et al.*, 2013).

In order to uncover multidimensional metabolic trajectories underlying a particular phenotype, different statistical methods can be used to establish a ‘biomarker profile’. Unlike other omics approaches, metabolites interact and are more likely to influence the concentrations of others, even those in disparate metabolic compartments. Intuitively this makes multivariate statistical methods more suited to analysing metabolic profiling data, however whether the choice is made for multi- or univariate statistical methods, the key aspect to take under consideration is to avoid introducing bias into a model, for instance by careful selection of training, test and validation sets, and utilization of robust methods for the identification of important metabolites in a model.

Future Directions for Metabolic Profiling

The future prospects of metabolic profiling do not solely relate to the information it provides, but more in its integration into global systems biology. Specifically, what it can provide for patient stratification in personalized medicine (Nicholson *et al.*, 2012b) and how it can be used in conjunction with other omic data for diagnosis, prognosis and treatment monitoring, as well as for prevention in precision medicine (Collins and Varmus, 2015). Specific attention will be focussed on understanding the environmental variability and trans-genomic interactions that together with the host genome determine the molecular phenotype (Li *et al.*, 2008; Nicholson *et al.*, 2011). This includes understanding how gut microbes are part of host metabolism and integrate these data for modelling metabolic reactions (Posma *et al.*, 2014) and metabolic signalling information (Rodriguez-Martinez *et al.*, 2017), and to better understand metabolism by studying the metabolic fluxes and regulation in a biological system (Zamboni *et al.*, 2015).

Owing to the data tsunami that the omic sciences create, the effective storage of biological samples in biobanks (Elliott *et al.*, 2008) as well as the storage of omic, clinical and other metadata (Haug *et al.*, 2013) has a major impact on future science. In the same light, reproducibility efforts (Fiehn *et al.*, 2016) of previous studies (Ward *et al.*, 2010) aim to address concerns about possible reproducibility issues in scientific research (Ioannidis, 2005). These approaches, either the effective storage of biological specimens for analysis at a later date by analytical techniques, publically available data sets that can be re-analysed using more sophisticated statistical methods and reproduction efforts of high profile studies, contribute to reducing effects of reporting bias.

Development and improvement of bioinformatic and statistical methods to make suitable for analysis of metabolic profiling data, for instance using linear-mixed effects models to correct for confounders as in GWAS (Listgarten *et al.*, 2012), or those tackling specific tasks such as expanding automated and robust data processing pipelines and tools to facilitate metabolite identification, are essential to understand the systems-level effects of metabolites and to deal with the high-dimensionality and collinearity of metabolic profiling data. In addition, the integration of metabolic profiling with other omic data such as metabolic Quantitative Trait Loci mapping and metabolic GWAS (Robinette *et al.*, 2012) or investigating the interplay between the microbiome and metabolism will play an important role in advancing health and understanding of the aetiology truly at a systems level (Johnson *et al.*, 2016).

Closing Remarks

Metabolic profiling has established itself as a field that can provide information about a biological system that are not possible using other systems biology methods. More focus on automated and robust processing pipelines, data analysis algorithms to reduce the level of bias and confounding in the model, development of new approaches to aid in the computational aspect of metabolite identification and efforts that aim to improve the reproducibility of research will increase the impact that metabolic profiling has in human health and disease.

Biographical Sketch

Joram Matthias Posma's work involves the development of new algorithms and methods to maximize information recovery from omic data including multivariate regression and classification algorithms, software for the interactive and immersive visualization of metabolic reaction network data, statistical spectroscopy methods for metabolite identification, and bioinformatic and statistical workflows for the analysis of metabolic profiling data. He is first author of publications that appeared in *Science Translational Medicine*, *The Lancet Diabetes & Endocrinology*, *Bioinformatics*, *Analytical Chemistry* and *Analytical and Bioanalytical Chemistry*, and is co-author of publications in *Nature Communications*, *Hypertension*, *Bioinformatics*, *Analytical Chemistry* and *Journal of Proteome Research*. He obtained his MSc in Chemistry *cum laude* from Radboud University Nijmegen in 2011 and his PhD in Bioinformatics and Clinical Medicine Research from Imperial College London in 2014. He is a Member of the Royal Society of Chemistry.

Metabolic Models

Jean-Marc Schwartz, University of Manchester, Manchester, United Kingdom

Zita Soons, Maastricht University, Maastricht, The Netherlands

Introduction

Metabolism is an essential part of living organisms, constituted by the set of biochemical reactions that process nutrients and produce the molecular components needed by cells to maintain themselves and grow. Metabolic reactions are biochemical transformations but most of them are not spontaneous, they are catalysed by enzyme proteins which are specifically adapted to process a precise transformation. Metabolic reactions have been studied since the 19th century using both *in vitro* and *in vivo* analyses, and are well characterised for many species. Therefore metabolism is well suited for the development of mathematical models, which are aimed at calculating the levels of flux going through metabolic reactions and the amounts of substrates and products used by these reactions.

Different types of metabolic models can be produced, which differ in their level of complexity and in the precision of their outcomes. In the following we explain the principle of the most important approaches for metabolic modelling, with a focus on those that have shown the greatest range of uses and applications.

Kinetic Models

Principle

Kinetic models are the most flexible type of metabolic models. They generally use differential equations to represent detailed mechanisms of enzymatic reactions and enable a detailed computation of reaction fluxes and metabolite concentrations over time.

The formulation of a kinetic model of a metabolic system uses two main types of relations. The first type are mass conservation equations, which reflect the fact that matter is conserved in any type of chemical transformation (Fig. 1). For each metabolite, the mass conservation equation is written by expressing that the change in the metabolite concentration is equal to the sum of all incoming reaction fluxes minus the sum of all outgoing reaction fluxes.

The second type of relations are kinetic equations, which are generally expressed in the form of ordinary differential equations. The kinetic equation expresses the dependence of the reaction rate (flux) on the concentration of metabolites participating in the reaction and any regulators. It is worth noting that if the reaction is reversible, the flux can take positive or negative values and the positive direction can be chosen arbitrarily; if the reaction is irreversible only positive values are allowed.

Types of Kinetic Equations

There are many types of possible kinetic equations, depending on the complexity of the reaction mechanism and the desired level of precision (Cornish-Bowden, 2004). The simplest type is mass action kinetics, in which the reaction rate is directly proportional to the concentration of substrate(s). While this relation is sometimes used due to its simplicity, it is only strictly valid for elementary chemical reactions and is generally not an accurate depiction of enzymatic reaction kinetics. In practice, when all enzyme active sites are occupied the reaction rate reaches a plateau determined by the amount of available enzyme, but this property is not captured by the mass action relation.

The Michaelis-Menten relation offers a more accurate depiction of enzymatic reaction kinetics, which captures the saturation property. It is based on the assumption that the enzyme forms a complex with the substrate in a reversible process, followed by an irreversible decomposition of the complex into enzyme and product; moreover the concentration of enzyme is assumed to be much lower than the concentration of substrate. More complex forms of the Michael-Menten relation can be derived depending on

Fig. 1 From metabolic network to kinetic model.

the number of substrates and products, the order of binding of different substrates to the enzyme-substrate complex, the presence of activators and inhibitors, and whether the reaction is reversible or not.

In the case of reactions with multiple substrates and products, it can be difficult to know the exact reaction mechanism and to derive the most accurate form of Michaelis-Menten equation. For this reason, generic forms of enzyme reaction kinetics have been proposed which are applicable to any type of reaction at the expense of simplifying assumptions. One of the most versatile forms is the convenience kinetics equation, which assumes random-order and reversible binding and dissociation of substrates with the enzyme (Liebermeister and Klipp, 2006).

Simulation and Applications

When the kinetic model is built, the time course of flux and concentration values is obtained by resolving the system of differential equations. This is generally not manually feasible, except for very simple systems, because of the mathematical complexity of equations. A number of computational tools are available that are more specifically targeted at simulating biochemical systems, in particular Copasi, CellDesigner, VCell (see “Relevant Website sections”).

The construction and use of kinetic metabolic models is challenging, not only because complex equations and numerous parameters need to be determined for their construction, but also because large amounts of quantitative experimental data need to be measured for their validation. For this reason, relatively few practical applications have been reported compared to other methods, despite the fact that such models have been made for a long time. For example, several kinetic models of yeast glycolysis were proposed which were validated against measured concentrations and fluxes, and were further used to explain glycolytic oscillations in yeast (Hynne *et al.*, 2001; Williamson *et al.*, 2012). Kinetic models were developed of the red blood cell and used to predict effects of enzymopathies (Jamshidi *et al.*, 2002), and of iron metabolism in order to simulate haemochromatosis (Mitchell and Mendes, 2013). The Grape software has been developed more specifically to facilitate the construction of large metabolic models using generic rate equations and to enable parameter estimation using ‘omics’ datasets (Adiamah *et al.*, 2010).

Petri Nets

Although they are generally not classified as a kinetic modelling method, Petri nets are another technique that can be used to simulate dynamic metabolic networks. Petri nets are a concept derived from informatics which is well suited for the modelling of biochemical reaction networks (Chaouiya, 2007). They are based on a bipartite graph representation consisting of *places* and *transitions*, connected by directed arcs. In a model of metabolic pathway, places correspond to metabolites and transitions correspond to enzymatic reactions. Each place holds a certain number of *tokens*, which represents the amount or concentration of the metabolite. When the required number of tokens is present, a transition is *fired* meaning that tokens of substrates are consumed and those of products are produced, in quantities defined by the weights of the arcs connecting them to the transition. This process represents a good analogy of what occurs in a metabolic reaction, therefore many concepts derived from Petri net theory have a real-world interpretation in metabolic networks (Baldan *et al.*, 2010). For example, steady-state flux distributions are the equivalent of *T-invariants* in Petri net theory, and elementary flux modes correspond to *minimal T-invariants*. Several models of metabolic pathways using Petri nets were developed, including both qualitative and quantitative models, for example of sucrose breakdown in potato, human iron metabolism, glycolysis in liver, etc.

Stoichiometric Models

Stoichiometric Matrix

Stoichiometric models are a class of metabolic models that do not use kinetic information but only rely on the mass conservation principle. Mass conservation is embedded in the stoichiometric coefficients of metabolic reactions, which indicate the number of molecules of each substrate and product needed to complete the transformation. For example in the adenylate kinase reaction:

two molecules of adenosine diphosphate (ADP) are transformed into one molecule of adenosine triphosphate (ATP) and one molecule of adenosine monophosphate (AMP).

For computational modelling, it is generally convenient to represent stoichiometric coefficients in the form of a matrix, where each column represents a reaction and each row a metabolic compound. For example the stoichiometric matrix of the adenylate kinase reaction becomes:

$$\begin{array}{c} \text{ADP} \\ \text{ATP} \\ \text{AMP} \end{array} \begin{bmatrix} -2 \\ 1 \\ 1 \end{bmatrix}$$

It is worth noting that the stoichiometric coefficient of the substrate (ADP) is negative, indicating that it is consumed by the reaction, and that of products (ATP and AMP) is positive, indicating that they are produced by the reaction. In the case of reversible reactions, an arbitrary positive orientation needs to be chosen.

Quasi Steady State Assumption

In a metabolic network, the stoichiometric matrix can be used to express mass conservation relations in a condensed form:

$$S \cdot v = \frac{dC}{dt}$$

where S is the stoichiometric matrix, v is the vector of reaction fluxes and C is the vector of metabolite concentrations.

The quasi steady state assumption consists in considering that metabolite concentrations do not change over time, then the previous equation becomes:

$$S \cdot v = 0$$

The advantage of this approach is to reduce the system to a set of linear equations, which can be solved according to standard linear algebraic techniques. In practice, this assumption is generally valid in biological systems because metabolism adjusts fast to changes in gene expression, therefore at any time metabolic fluxes can be considered balanced (Fell, 1997). Changes in the flux distribution over time can still be modelled as a succession of steady states resulting from changing boundary conditions. Moreover, it is generally admitted that internal metabolites cannot accumulate or deplete over a long period of time in living systems (Reimers and Reimers, 2016).

Flux Balance Analysis

The linear system of equations obtained from the quasi steady state assumption is generally underdetermined, which means that there is an infinite number of possible solutions. It is possible to reduce the range of possible solutions by adding an assumption of optimality: living organisms do not behave randomly but are expected to have evolved to maximise the production of certain compounds that are essential for their survival and growth. The production of these compounds can be represented by an artificial biomass reaction whose composition reflects the overall molecular composition of the cell. In some cases a different objective is more relevant, for example ATP production may be maximised in order to optimise energetic availability, or in a metabolic engineering context one may seek to maximise the production of certain compounds of biotechnological interest. In all cases, the fluxes leading to the production of objective compounds can be represented by an *objective function* Z . The optimisation of Z is added as a constraint to the linear system of equations defined by $S \cdot v = 0$, resulting in a considerable reduction of the solution space. Additional constraints apply to metabolic fluxes, such as the maximum capacity of enzymes which sets an upper limit on the allowable flux, and the irreversibility of some reactions which forbids the flux from running in the reverse direction.

Taken together with the conservation of mass in steady state $S \cdot v = 0$, the optimisation of the objective function Z , and information about the cellular environment such as uptake rates of certain nutrients, this set of constraints define the method of Flux Balance Analysis (FBA) (Orth *et al.*, 2010). These equations can be solved by *linear programming* algorithms using computational tools such as the COBRA toolbox (Schellenberger *et al.*, 2011) (see "Relevant Websites" section).

A major advantage of FBA is that this method is fast enough to calculate flux distribution in genome-scale metabolic models containing several thousands of reactions. For this reason, FBA has been one of the most widely used methods for metabolic modelling and has led to numerous applications. Among others it has been used for determining optimal growth conditions of organisms, effects of environmental changes and mutations, understanding how certain pathogens rely on their host's metabolism, determining drug targets, designing optimised strains to produce compounds of interest for biotechnology, etc. (Bordbar *et al.*, 2014; Chapman *et al.*, 2015).

Range of Optimal Solutions

Although the FBA algorithm results in a unique value of the objective function Z , there may still be a range of flux distributions satisfying the optimal constraints of FBA. For example, flux may be distributed along several internal branches in the metabolic network that are neutral in terms of the objective function. The method of Flux Variability Analysis was developed to calculate the upper and lower flux values of all reactions that can lead to the optimal value of Z (Gudmundsson and Thiele, 2010). Besides making it possible to identify degeneracies leading to multiple solutions, this method can also be used to identify blocked reactions, whose flux is constrained to zero due to inaccuracies in the model or unavailable nutrients.

However, any combination of fluxes comprised between the bounds of FVA does not necessarily make a feasible flux distribution. Hence, other methods were developed to sample feasible flux distributions that optimise the objective function, making it possible to get a comprehensive view of the range of possible solutions (Schellenberger and Palsson, 2009).

A different possibility to reduce the multiplicity of solutions is offered by the method of parsimonious FBA (pFBA). pFBA adds to standard FBA an assumption of minimising the overall flux in the metabolic network, which amounts to minimise the amount of enzyme required. This assumption may not hold true in all cases but was shown to produce good agreement with experimental data, in particular for evolved strains where there is competition for fastest growth (Lewis *et al.*, 2010).

Genome-Scale Metabolic Models

Advances in genome sequencing have made it possible to get a good knowledge of the enzyme content of many species. This in turn has made it possible to reconstruct the full set of metabolic reactions occurring in several of these species, which are then called genome-scale metabolic models (GEMs). A GEM contains not only all known metabolic reactions with their substrates and stoichiometries, but also all the genes and proteins associated to these reactions. Some methods were developed to automate in part the reconstruction process of GEMs (Swainston *et al.*, 2011), but a high level of manual input and curation is generally needed to achieve the best quality (Feist *et al.*, 2009). A functional model must not only integrate as many as possible of the known metabolic reactions of the species, but also be able to produce all the essential cellular compounds under known experimental growth conditions.

GEMs are currently available for a range of species, including bacteria, archaea, fungi, plants and human cell types. Among the most complete and curated are the models of *E. coli* (Orth *et al.*, 2011), yeast (Heavner *et al.*, 2013) and human (Swainston *et al.*, 2016). These models were developed through several iterations over years, and the latter two involved a collaborative approach associating several research groups around the world. More recently, methods were developed that use transcriptomics or proteomics data to construct specific models for different types of human cells or tissues (Uhlén *et al.*, 2015).

GEMs have been used for numerous types of applications. They greatly facilitate the interpretation of high-throughput data such as transcriptomics, proteomics and metabolomics data, since overlaying them on a GEM can show what type of metabolic functions are active (Oberhardt *et al.*, 2009). They can be used to understand metabolic functions and their regulation in an organism, effects of environmental or nutritional changes on an organism's growth or adaptation, interactions between multiple species in an ecosystem, and define genetic manipulations in order to improve some functionalities of an organism in metabolic engineering.

Elementary Mode Analysis

Principle

Constrained based methods such as FBA are biased towards a certain biological objective. Pathway analysis has the advantage of identifying all pathways inherent to a metabolic network. A popular method for pathway analysis, Elementary Modes (EMs), identifies all admissible minimal pathways connecting substrates with biomass and products inherent to a metabolic network (Schuster *et al.*, 1999). Here, admissible means that the pathway satisfies internal mass balances and the direction constraints on reactions arising from thermodynamic conditions. For example, in the toy network shown in Fig. 2, four EMs exist, which cannot be further decomposed. EM₁ presents a cycle between metabolites B and C with no net production or consumption. EM₂ presents the formation of extracellular metabolite D from substrate Aext. EM₃ and EM₄ produce biomass from A through either reaction F6 or through reactions F7 and F9.

In addition to EMs, several other concepts such as Extreme Pathways (EPs) (Schilling *et al.*, 2000) and Generating Vectors (GVs) (Wagner and Urbanczik, 2005) are promising. EP analysis identifies the minimal set of independent pathways through the network, which is a subset of the EMs. GV are in turn a subset of the EPs. These methods for pathway analysis have been evaluated by several authors, amongst others (Klamt and Stelling, 2003). Several tools have been developed to enumerate the pathways, amongst others the widely used METATOOL (Pfeiffer *et al.*, 1999) and efntool (Terzer and Stelling, 2008).

Large-Scale Enumeration

Despite improvements in the algorithms for computation of EMs, EPs and GV, their application to larger metabolic networks has been hampered by the combinatorial explosion in the number of modes as the network size increases. The enumeration of the complete set of EMs for genome-scale networks has been infeasible, and perhaps even undesirable due to the hardly manageable number of modes that would be generated. An alternative approach is the enumeration of a subset of pathways representing the

Fig. 2 Control effective flux analysis on an example network. **(A)** Toy network modified from (Rabinowitz and Vastag, 2012). **(B)** Flux balance equations **(C)** Elementary modes and CEFs.

complete system. Examples are enumeration of the shortest pathways (De Figueiredo *et al.*, 2009), enumeration of pathways including a specific target reaction (Kaleta *et al.*, 2009a,b), enumeration based on available measurements (Jungers *et al.*, 2011), elementary flux patterns (Kaleta *et al.*, 2009a,b), decomposition of the network in modules (Schuster *et al.*, 2002; Schwartz *et al.*, 2007) and random sampling (Machado *et al.*, 2012).

Applications

EMs have been used to understand the cellular metabolism through analysis of the network structure, regulations and characterization of all possible phenotypes (Çakir *et al.*, 2007; Schuster *et al.*, 1999, 2002; Stelling *et al.*, 2002; Soons *et al.*, 2013; Schwartz *et al.*, 2015). Examples of other applications of pathway analysis are the determination of minimum medium requirements (Schilling and Palsson, 2000) and the derivation of reduced kinetic models (Provost and Bastin, 2004). They also play an essential role in the development of model-based metabolic engineering strategies for strain optimisation by identification of suitable intervention targets (Hädicke and Klamt, 2010; Trinh *et al.*, 2008; Boghigian *et al.*, 2010). Of particular interest, Hädicke and Klamt (2011) proposed a gene deletion strategy based on minimal cut sets to identify a minimal set of knockouts disabling the operation of a specified set of target elementary modes, while keeping a set of desired modes.

Control Effective Fluxes and Structural Fluxes

Structural fluxes combine the advantages of both objective function-centred and pathway enumeration-centred approaches. They account for a biological objective function and are derived from the enumeration of all pathways in a given metabolic network. Structural fluxes are inspired from the concept of control effective flux (CEF) to understand changes in transcriptional regulation (Stelling *et al.*, 2002). In the original formulation of CEF, the efficiency of each elementary mode i is defined as the ratio of EM's output (the cellular objective) to the investment required to establish the EM (the sum of the absolute flux values in the EM) for a specific carbon source:

$$\varepsilon_i = \frac{Y_i^{\text{objective}}}{\sum_k |e_i^k|} \quad (1)$$

The control effective flux of each reaction k is then obtained by the weighted average of the product of mode-specific efficiencies and reaction-specific fluxes over the sum of all mode efficiencies:

$$CEF_k = \frac{1}{Y_{X/S}^{\text{max}}} \cdot \frac{\sum_i \varepsilon_i \cdot |e_i^k|}{\sum_i \varepsilon_i} \quad (2)$$

where $Y_{X/S}^{\text{max}}$ denotes the maximum yield obtained for the specified cellular objective.

In order to find a measure that can predict fluxes across mutants and for growth on multiple substrates, Soons *et al.* (2013) and Schwartz *et al.* (2015) proposed three modifications in Eqs. (1)–(2) and thereby introduced Structural Fluxes. In summary, the yield is computed towards total substrate uptake (in terms of C-moles or molecular weight) and an additional normalization was added to account for networks of different sizes.

As an example, we determined the yields, efficiencies and CEFs for the toy network in Fig. 2(C) with biomass as the cellular objective (reaction Fbio) and uptake of external metabolite A as the input (reaction F1). Both EM₃ and EM₄ produce biomass with the same yield towards the substrate uptake reaction F1 (1/4). EM₄ involves one additional enzyme (through F7 and F9) compared to EM₃ (through F6) and is hence less efficient in terms of investment of enzymes (Eq. (1)). This is reflected by a slightly higher CEF for reaction F6 compared with F7 and F9. In real life networks, these trade-offs may be for instance presented in cancer cells by a high ATP yield per substrate for the TCA cycle, but also high investment costs in the number of enzymes in comparison with aerobic glycolysis.

Future Directions

As procedures for building genome-scale metabolic models are getting well established and the number of available models is growing, new research directions aim at enriching metabolic models with additional information. Thermodynamics plays an important role for metabolic reactions, since the energy levels of substrates and products determine if a reaction is feasible or not. Several studies have attempted to integrate thermodynamic data into metabolic models in order to estimate metabolite concentrations and determine reaction directionality (Ataman and Hatzimanikatis, 2015), determine which elementary modes are feasible or not (Gerstl *et al.*, 2016) and discover reactions that favour growth at higher or lower temperature (Paget *et al.*, 2014).

Another direction to enrich metabolic models is to incorporate transcriptional regulation mechanisms. The metabolic flux is controlled by enzymes which are themselves regulated by transcription factors and other regulatory mechanisms, therefore these interactions must be taken into account to achieve better quantitative predictions. The construction of integrated transcriptional and metabolic models has started, using both kinetic and constraint-based approaches, and constitutes an important objective for future research (Imam *et al.*, 2015).

Eventually, metabolic models from different species need to be connected. In biological environments ranging from human microbiota to global ecosystems, different organisms exchange compounds with each other or compete for resources. The behaviour of each species cannot be fully determined without considering its interactions with other species, which requires moving from species-level to community-level metabolic models (Biggs *et al.*, 2015).

Closing Remarks

Metabolic models have shown broad utility for both biomedical and biotechnological applications. Different approaches can be used to model metabolic systems and each of them has specific advantages and limitations, which is why it is important to choose the best suited technique depending on the expected outcomes of the model. Metabolic reactions are not isolated but are interconnected with other cellular processes, therefore a challenge in any model is often to define suitable boundaries; this choice should always be directed by biological knowledge to include enough but no superfluous components to explain the expected biological functions and reach the desired level of precision.

Biographical Sketch

Jean-Marc Schwartz is a senior lecturer in the Faculty of Biology, Medicine and Health at the University of Manchester. He has been working for 20 years at the interface between physical and biological sciences, focusing on computational techniques for modelling biological systems. He holds a PhD in computer engineering from Laval University and has worked as a postdoctoral researcher at the Kyoto University Bioinformatics Center, which develops the KEGG genomic and metabolic database, before joining the university of Manchester. His research applies a range of computational techniques, including kinetic, logical and constraint-based modelling, to understand the functioning of biological pathways and cellular systems. Of particular interest are the development of metabolic models of human cells to understand diseases such as cancer, and of microorganisms to discover how they are affected by environmental change and develop biotechnological applications.

Zita Soons works as an assistant professor at the Department of Surgery of Maastricht University, The Netherlands. Her main topic is the integration of stable isotope labelling and MS-Imaging to understand cancer metabolism. She is a specialist in computational systems biology of human and microbial metabolism. In previous jobs, she integrated empirical data on metabolism with metabolic models ranging from biotechnological production to cancer. She received a personal grant to work as a postdoctoral researcher at the University of Minho (Portugal) in 2009–2012, which also involved a stay at the European Molecular Biology Laboratory in Heidelberg (Germany). She received a PhD degree on systems and control theory at Wageningen University/Netherlands Vaccine Institute (The Netherlands). In her current job, she also enjoys incorporating the latest advances in her field of research into teaching.

Introduction

Proteins

Proteins are one of the important biological macromolecules built from 20 amino acids. They perform several functions in living organisms such as enzymatic catalysis, transportation of ions and molecules, antibodies and regulation of cellular and physiological activities. The functions of proteins mainly depend on their three-dimensional (3D) structures. Currently, more than 130,000 structures of proteins and their complexes are deposited in Protein Data Bank, PDB ([Burley et al., 2017](#)) whereas the amino acid sequences are known for more than 80 million proteins ([The UniProt Consortium, 2017](#)). [Anfinsen \(1973\)](#) stated that the amino acid sequence of a protein contains all the information necessary to specify its 3D structure. Deciphering the 3D structure of a protein from its amino acid sequence is a longstanding goal in molecular and computational biology. Further, the structures of proteins and their complexes provide ample insights to understand inter-residue interactions, protein folding mechanisms, folding and unfolding rates, stability of protein structures, stability upon mutations, recognition mechanism of protein-protein, protein-nucleic acid and protein-ligand complexes, and structure-based drug design ([Gromiha, 2010](#)). [Fig. 1](#) illustrates the major themes covered in this review.

Fig. 1 Flowchart showing various aspects of computational studies on protein structures.

Fig. 2 For major levels of protein structures. Adopted from Gromiha, M.M., 2010. Protein Bioinformatics. Academic Press, New Delhi.

Structural Organization of Proteins

Protein structures are usually described in terms of four levels: primary, secondary, tertiary and quaternary (**Fig. 2**). Primary structure describes the linear sequence of amino acid residues in a protein. Secondary structure is the regular, recurring arrangements of adjacent amino acid residues in a polypeptide chain and major secondary structures are α -helices and β -strands.

They are formed by hydrogen bonds between amide hydrogens and carbonyl oxygens of the peptide backbone. Tertiary structure provides atomic and spatial level information of all residues in a protein. Quaternary structure refers to the association of two or more polypeptide chains into a multisubunit or an oligomeric protein.

Classification of Proteins Based on Structure and Function

Proteins fall into three major groups: fibrous, globular and membrane proteins. Fibrous proteins are insoluble in solvents and the polypeptide chains are arranged in long strands or sheets. They play important structural roles, providing external protection, support and shape. Examples of fibrous proteins include α -keratin, the major component of hair and nails, and collagen, the major protein component of tendons, skin, bones and teeth.

Globular proteins are important for their functional roles and the amino acid residues in a globular protein fold to a proper, unique three-dimensional structure. Globular proteins are classified into four structural classes, namely, all- α , all- β , $\alpha + \beta$ and α/β (**Fig. 3**). The all- α and all- β classes are dominated by α -helices and β -strands, respectively. The $\alpha + \beta$ and α/β classes contain both α -helices and β -strands. In $\alpha + \beta$ class, helices and strands usually segregate while they are mixed together in the α/β class.

Proteins that are embedded in biological membranes are called membrane proteins and they serve as receptors, transporters and signaling molecules. Membrane proteins are of two kinds: transmembrane helical proteins that span the cellular membrane with α -helices and transmembrane β -sheet proteins that traverse the outer membrane of gram negative bacteria with β -strands. In most of genomes (bacteria, archaea and eukaryota), 20–30% of the proteins are estimated to be membrane proteins (Almeida *et al.*, 2017) and are identified as targets for drug design.

Structure Databases for Proteins and Their Complexes

The Protein Data Bank (PDB) is a unique resource for experimentally determined structures of proteins and their complexes (Burley *et al.*, 2017). Utilizing the information available in PDB, several secondary databases have been developed for structural classes and architectures of proteins such as SCOP (Structural classification of proteins) (Andreeva *et al.*, 2008), CATH (Class, Architecture, Topology and Homologous superfamily) (Sillitoe *et al.*, 2015), PDBTM (Protein Data Bank of Trans Membrane proteins) (Kozma *et al.*, 2013), and protein-protein, protein-nucleic acid, protein-carbohydrate and protein-ligand complexes. **Table 1** lists the available structural databases for proteins and their complexes.

Analysis of Protein 3D Structures

The availability of protein 3D structures paves the way for researchers to derive the principles governing the folding and stability of proteins, binding sites in protein complexes and development of several structural parameters. Further, various structure-based

Fig. 3 Major structural classes of globular proteins.

parameters for proteins and physicochemical, energetic and conformational parameters of amino acids have been developed, using 3D structures of proteins deposited in PDB.

Assignment of Secondary Structure and Solvent Accessibility

Kabsch and Sander (1983) utilized the hydrogen bonding pattern in protein structures and assigned secondary structures to each residue in a protein. Lee and Richards (1971) proposed the concept of accessible surface area (ASA) to locate the interior seeking and exposed residues in a protein. ASA is defined as the locus of the centre of the solvent molecule as it rolls over the van der Waals surface of the protein. Generally, water is assumed to be the solvent, represented by a sphere of radius 1.4 Å. The solute molecules are represented by a set of interlocking spheres of appropriate van der Waals radii assigned to each atom and the solvent molecule is rolled along the envelope of the van der Waals surface at planes conveniently sectioned. Several methods have been proposed to compute the solvent accessibility of amino acid residues from protein structures (Gromiha and Ahmad, 2005). These programs provide numerical data for accessible surface area and hence Ahmad *et al.* (2004) developed a tool, ASAview to represent them pictorially. The ASA values for the Zif268 zinc finger protein are shown in Fig. 4 as spiral circles with different colors to visualize the exposed and interior seeking residues, based on their chemical behavior and ASA values (see Relevant Websites section).

Residue-Residue Contacts

The contacts between amino acid residues in a protein as well as with the surrounding medium mainly dictate the folding and stability of protein structures. These contacts influence all major non-covalent interactions such as hydrophobic, electrostatic, hydrogen bonding and van der Waals interactions as well as disulfide bonds (Fig. 5). Inter-residue contacts are classified as short, medium and long-range, based on the location of the contacting residues in the 3D structure as well as in the sequence (Gromiha and Selvaraj, 2004). The information about preferred contacts in protein structures has been used to understand the residue-residue co-operativity in protein folding as well as to develop contact potentials.

The most widely used approach for deriving contact potentials is computing frequencies of sequence and structure features, and converting them into free energies using the following relation

$$\Delta G = -kT \log(f) \quad (1)$$

where k is the Boltzmann's constant, f denotes frequencies and T is the temperature (Sippl, 1990). Further, contacts between amino acid residues in proteins structures reveal the importance of specific contact pairs in different structural classes and folding types of globular proteins, α -helical and β -barrel membrane proteins, mesophilic and thermophilic proteins (Gromiha, 2010).

Non-Covalent Interactions in Protein Structures

Hydrophobic interactions play a dominant role in the folding and stability of protein structures. Hydrophobicity is inversely proportional to ASA and hence, hydrophobic free energy is estimated indirectly using the computable parameter, ASA. It is computed by (Gromiha, 2010):

$$G_{hy} = \sum \Delta \sigma_i [A_i(\text{folded}) - A_i(\text{unfolded})] \quad (2)$$

where, i stands for different atom types, and $A_i(\text{folded})$ and $A_i(\text{unfolded})$ are the ASA of each atom type in the folded and

Fig. 4 Graphical representation of ASA values of amino acid residues in Zif268 zinc finger protein (PDB-id: 1AAY).

unfolded (extended) states of the protein, respectively. $\Delta\sigma_i$ refers to atomic solvation parameters obtained by fitting ΔG and ASA in extended conformation of each atom type in the 20 amino acid residues. It is calculated as:

$$\Delta G = \sum \Delta\sigma_i A_i \quad (3)$$

Electrostatic free energy is generally computed by Coulomb's law using the charge of interacting atoms and the distance between them.

$$E_{es} \propto q_i q_j / r_{ij} \quad (4)$$

where q_i and q_j are the effective partial charges for atoms i and j , respectively and r_{ij} is the distance between them.

Hydrogen bonds are responsible for the formation and stability of protein secondary structures, α -helices and β -strands. Hydrogen bonds are formed between two electronegative atoms mediating with a hydrogen atom. The contribution of hydrogen bonds is computed using the distance between the heavy atoms and the angle formed by the three atoms involved.

van der Waals interaction energy is generally computed using Lennard-Jones 6–12 potential:

$$G_{vw} = \left(A_{ij}/r_{ij}^{12} - B_{ij}/r_{ij}^6 \right) \quad (5)$$

Fig. 5 Various non-covalent interactions and disulfide bonds in protein structures.

where $A_{ij} = \epsilon_{ij}^* (R_{ij}^*)^{12}$ and $B_{ij} = 2 \epsilon_{ij}^* (R_{ij}^*)^6$; $R_{ij}^* = (R_i^* + R_j^*)$ and $\epsilon_{ij}^* = (\epsilon_i^* \epsilon_j^*)^{1/2}$, R^* and ϵ^* are, respectively, the van der Waals radius and well depth.

In addition, cation- π interactions (Dougherty, 1996) are recognized to play an important role in globular, membrane, DNA binding, mesophilic and thermophilic proteins as well as in the recognition of protein-protein complexes. These are formed by the interaction between the positive charged residues Lys and Arg and aromatic residues, Phe, Trp and Tyr. Cation- π interactions in protein structures have been identified using distance and energy-based criteria: (i) distance between the cationic group and the centers of all aromatic rings should be less than 10 Å and (ii) the interaction energy between the positive charged and aromatic residues (sum of electrostatic and van der Waals) should be less than -2 kcal/mol.

Amino Acid Properties Derived from Protein Structural Data

Protein structures have been used to derive several properties for amino acid residues as well as the whole protein.

- (i) Medium and long-range contacts: Medium-range contacts refer to the contacts between amino acid residues within the distance of 8 Å and a sequence separation of three or four residues while the sequence separation is more than four residues in long-range contacts.
- (ii) Number of neighbouring residues: For each central residue, number of contacting residues within a specific cut-off distance (8 Å).
- (iii) Surrounding hydrophobicity: For a specific residue, this is the sum of the experimental hydrophobicity indices of residues, which occur within a sphere of radius 8 Å (Ponnuswamy, 1993). It is estimated using

$$H_p(i) = \sum_{j=1}^{20} n_{ij} h_j \quad (6)$$

where, n_{ij} is the total number of surrounding residues of type j around i th residue of the protein and h_j is the experimental hydrophobic index of residue type j in kcal/mol (Jones, 1975).

- (iv) Transfer free energy: The ASA of each residue provides information about the occurrence of that residue either in the interior of the protein or the surface and the ratio between them is used to compute the partition coefficient (f), which has

been used to derive the transfer free energy:

$$\Delta G_t = -RT \ln f \quad (7)$$

- (v) Buriedness and reduction in accessibility: Buriedness is defined as the ratio between the number of residues (of type *i*) in the interior of the protein to the total number of residues (of type *i*) in a protein. Similarly, reduction in accessibility is given by:

$$\langle R_A \rangle = A^0 - \langle A \rangle / A^0, \quad (8)$$

where, A^0 and $\langle A \rangle$ represent the accessible area in the unfolded (extended) and folded states of the protein, respectively.

- (vi) Flexibility: This parameter deals with the root mean square displacement of amino acid residues and is also related to the temperature factor (B factor) of amino acid residues in protein structures.
- (vii) Numerical values for amino acid properties: Kawashima *et al.* (2008) developed a database, AAindex, which contains the numerical indices for 516 physicochemical and biochemical properties of amino acids and pairs of amino acids. Gromiha *et al.* (1999a) compiled a set of 49 physicochemical, energetic and conformational properties of amino acid residues for understanding the folding and stability of proteins.

On the other hand, several parameters have been derived for a whole protein or protein chains.

- (viii) Contact Order: This measure reflects the relative importance of local and non-local contacts to the native structure of a protein (Plaxco *et al.*, 1998). It is defined as

$$CO = \sum \Delta S_{ij} / L \cdot N, \quad (9)$$

where ΔS_{ij} is the sequence separation between contacting residues *i* and *j* within a distance of 6 Å between any heavy atoms, *L* is the total number of residues in the protein and *N* is the total number of contacts.

- (ix) Long-range order: A knowledge of long-range contacts (contacts between two residues that are close in space and far in the sequence) in protein structure (Gromiha and Selvaraj, 2001) defines long-range order:

$$LRO = \sum n_{ij} / N; \quad n_{ij} = 1 \text{ if } |i - j| > 12; = 0 \text{ otherwise,} \quad (10)$$

where *i* and *j* are two contacting residues in space within a distance of 8 Å and *N* is the total number of residues in a protein.

- (x) Multiple contact index: When a residue has multiple contacts, the multiple contact index is used for computing long-range order (Gromiha, 2009) and is defined as

$$n_{ci} = \sum n_{ij}; \quad n_{ij} = 1 \text{ if } r_{ij} < 7.5 \text{ Å; } |i - j| > 12 \text{ residues; } 0 \text{ otherwise}$$

$$MCI = \sum n_{mi} / N; \quad n_{mi} = 1 \text{ if } n_{ci} \geq 4; 0 \text{ otherwise} \quad (11)$$

where n_c is the number of contacts for each residue, and r_{ij} is the distance between the residues *i* and *j*.

Nagarajan *et al.* (2016) developed a web-based tool, PDBparam, to derive a set of more than 50 features on four different themes, viz., (i) identification of binding sites, (ii) inter-residue interactions, (iii) secondary structure propensities and (iv) physicochemical properties. Similar web servers have also been developed for various weak and strong interactions, PIC (Tina *et al.*, 2007), contact between amino acid residues, CMWeb (Kozma *et al.*, 2012) and binding site residues in protein-DNA complexes, INTAA (Galgonek *et al.*, 2017).

Prediction of Protein Tertiary Structures

Deciphering the native conformation of a protein from its amino acid sequence, termed as the “protein folding problem” is a longstanding challenge in molecular and computational biology. Several methods have been proposed to achieve the goal and the performances of these methods have been critically evaluated by the forum, Critical Assessment of Techniques for Protein Structure Prediction (CASP), using blind prediction experiments. The developments of reliable methods are outlined in this section. Three major approaches namely, homology modeling, fold recognition and *ab initio* have been developed for the prediction of protein tertiary structures. In recent years, the above three approaches have been grouped into template-based modeling and template-free modeling (Li *et al.*, 2015; Källberg *et al.*, 2012; Xu *et al.*, 2009).

Homology Modeling

Homology modeling, also known as comparative modeling, is based on the biological fact that when two sequences share high similarity/identity, their respective structures are also similar. In this method, the 3D structure of a protein is obtained with the following steps: (i) for a given target sequence, identifying the proper template using BLAST search, (ii) sequence alignment (iii) alignment corrections to ensure the conserved or functionally important residues are aligned, (iv) backbone generation (v) loop modeling, (vi) side chain modeling using rotamer libraries, (vii) optimizing the model using energy minimization and (viii) validating the model by stereochemical evaluation using the residues in the allowed regions of Ramachandran plot as well as favourable energies. MODELLER (Webb and Sali, 2014) is one of the widely used computational tools for predicting protein 3D

structures using homology modeling. MaxMod, PyMod, and PRIMO are other recent methods/servers for homology modeling and their URLs are included in [Table 1](#).

Fold Recognition

If the sequence identity between the target sequence and template structures fall below 30%, homology modeling methods may not be able to produce a reliable model and under such situations fold recognition methods are used for prediction ([Buchan and Jones, 2017](#); [Lhota and Xie, 2016](#); [Jo et al., 2015](#)). These methods follow different steps to predict the 3D structure of a protein, which include (i) advanced sequence comparison methods, (ii) comparison of predicted secondary structure strings with those of known folds, (iii) tests of the compatibility of sequences with 3D folds and (iv) the use of human expert knowledge. Consequently, several methods and web servers have been developed for fold recognition such as, 3D-1D profiles ([David et al., 2004](#)), GenTHREADER ([Jones, 1999](#)), MUSTER ([Wu and Zhang, 2008](#)), ORION ([Ghouzam et al., 2016](#)), Phyre2 ([Kelley et al., 2015](#)), TMFoldRec ([Kozma and Tusnady, 2015](#)), DescFold ([Yan et al., 2009](#)) and DN-Fold ([Jo et al., 2015](#)). [Table 1](#) includes the web addresses of these servers.

Ab Initio Protein Structure Prediction

Ab initio prediction methods consider all bonded and non-bonded interactions involved in the process of folding, and choose the structure with lowest free energy. This approach is based on the ‘thermodynamic hypothesis’, which states that the native structure of a protein is the one for which the free energy achieves the global minimum. Two major components to *ab initio* prediction are (i) devising a scoring function that can distinguish between correct (native or native-like) structures from incorrect ones and (ii) a search method to explore the conformational space. One of the best performing methods for *ab initio* structure prediction is the Rosetta algorithm ([Simons et al., 1997](#)). Several other recent methods include I-TASSER ([Roy et al., 2010](#); [Yang et al., 2015](#)), Robetta ([Kim et al., 2004](#)), EVfold ([Marks et al., 2011](#)), CABS-fold ([Blaszczyk et al., 2013](#)), QUARK ([Xu and Zhang, 2012](#)), PEP-FOLD ([Thevenet et al., 2012](#); [Shen et al., 2014](#)) and Bhageerath ([Jayaram et al., 2014](#)) ([Table 1](#)).

Modeling on the Web

Few 3D structure prediction methods are available online with user friendly interface. SWISS-MODEL is one of the widely used comparative protein modeling servers to predict the structure for a given amino acid sequence directly ([Bienert et al., 2017](#)). It has different options such as (i) ‘first approach mode’, which requires only an amino acid sequence of a protein; the server automates subsequent steps including template selection, alignment and model building, (ii) ‘alignment mode’, which is the modeling process based on a user-defined target-template alignment and (iii) ‘project mode’ in which complex modeling tasks can be handled.

Protein Folding Kinetics

Many small proteins are known to fold rapidly by simple two-state kinetics and the mechanism of protein folding has been elaborately addressed with folding rates and Φ -value analysis. Φ -value is given by the equation:

$$\Phi_{\#} = \Delta\Delta G_{\#-U} / \Delta\Delta G_{F-U} \quad (12)$$

where $\Delta\Delta G_{F-U}$ is the change in stability between the folded (F) and unfolded states (U), and $\Delta\Delta G_{\#-U}$ is the energy difference between mutant and wild type in the transition state, #. $\Phi=0$ corresponds to no structure formation in the transition state as in the unfolded state and a Φ value of 1 is interpreted that the residue has a native like structure in transition state ([Itzhaki et al., 1995](#)). The analysis of experimental Φ values of 296 mutants in seven single domain proteins showed that more than 82% of them exhibit a Φ value below 0.6 ([Raleigh and Plaxco, 2005](#)). In addition, negative Φ values are interpreted as mutations which stabilize the folding transition state while it destabilizes the native state ([De los Rios et al., 2005](#)).

Folding Nuclei

The residues with high Φ values form folding nuclei in protein structures, which mediate important interactions for folding and assembly of their native states ([Dobson, 2003](#)). Folding nuclei could be computationally identified using different techniques: (i) searching free-energy saddle points on a network of protein unfolding pathways, (ii) elucidating the correspondence between conserved hydrophobic positions in amino acid sequences and folding nuclei, (iii) computing the conservation scores of amino acid residues based on physicochemical properties and (iv) coupling ensembles of pathways with the lowest effective contact order and identifying contacts that are crucial for folding.

Protein Folding Rates

Protein folding rate is a measure of the slow/fast folding of a protein from its unfolded state to the native 3D structure. The data for folding rates for proteins and their mutants are available in literature ([Gromiha, 2010](#); [Chaudhary et al., 2015](#)).

Relating Protein Folding Rates Using Structural Parameters

Several structure-based parameters have been proposed to understand and predict protein folding rates. [Plaxco *et al.* \(1998\)](#) proposed the concept of contact order (CO) by estimating the average sequence separation of all contacting residues in the native state within a distance of 6Å normalized with total number of contacts and total number of residues. [Gromiha and Selvaraj \(2001\)](#) considered only the long range contacts with a sequence separation of 12 residues, which are within 8Å limit and proposed the concept of LRO. [Istomin *et al.* \(2007\)](#) showed that LRO is the only parameter that shows good correlation in all structural classes of proteins. Further, protein folding rates are well studied with total contact distance, first principles of protein folding, combination of CO and stability, topomer search model, topological properties of protein conformations, cliquishness, multiple contact index, helix parameter, n-order contact distance and chain connectivity due to crosslinks ([Gromiha, 2010](#)).

Prediction of Protein Folding Rates From Amino Acid Sequence

The analysis of the relationship between amino acid properties and protein folding rates showed a poor correlation between them. On the other hand, the secondary structure content of a protein and chain length showed a linear relationship with protein folding rates. Although chain length showed a good inverse correlation with the folding rates of three-state proteins no correlation between them was observed in two-state proteins ([Galzitskaya *et al.*, 2003](#)).

[Punta and Rost \(2005\)](#) predicted amino acid contacts using amino acid sequence and utilize the information to predict protein folding rates using the concept of long-range order. We have developed multiple regression models for predicting the folding rates of protein using amino acid properties ([Gromiha *et al.*, 2006](#)). Furthermore, protein folding rates are predicted with amino acid composition, rigidity and quadratic response surface models, n-order contact distance, secondary structure, solvent accessibility, compression capability of protein sequence, reactivity of proteins in solvents, contact surface of the unfolded chain and solvent, Gibbs free energy of hydration in denatured proteins, the average range of amino acid contact, the polarity value of amino acids, number of torsion angles of the side chain and residue-level coevolutionary information. The different algorithms for predicting the folding rates of proteins have been detailed in recent review articles ([Gromiha, 2010](#); [Gromiha and Huang, 2011](#); [Chang *et al.*, 2015](#)).

Prediction of Protein Folding Rates Upon Mutation

Amino acid substitutions may accelerate or decelerate the folding rate of a protein and it mainly depends on the location and type of mutations. [Huang and Gromiha \(2010\)](#) proposed the first approach to distinguish between accelerating and decelerating mutants using amino acid properties. The method has been extended further to predict the real value change in folding rates ([Huang and Gromiha, 2012](#)). The integrated approach using secondary structure information, location of mutants in a protein as well as the distribution along the sequence is reported to substantially improve the prediction accuracy of protein folding rate change upon mutation ([Chaudhary *et al.*, 2015](#); see Relevant Websites section). The analysis also showed that folding rate is primarily influenced with hydrophobicity, emphasizing the dominant influence of hydrophobic effect during the folding process. [Mallik *et al.* \(2016\)](#) utilized residue-level coevolutionary information for predicting protein folding rates upon mutations.

Protein Stability

Protein stability (ΔG) is the net balance between free energies in the folded and unfolded states. While the folded state is stabilized through disulphide bonds and non-covalent interactions, hydrophobic, electrostatic, hydrogen bonding and van der Waals interactions, the unfolded state is influenced by entropy. However, the difference between the folded and unfolded states is marginal and ΔG lies in the range of 5–25 kcal/mol.

Thermodynamic Database for Proteins and Mutants

[Gromiha *et al.* \(2016\)](#) compiled the data on stability of proteins and mutants from the literature and developed a database, ProTherm, which contains the thermodynamic parameters for more than 25,000 normal (or wild-type) and mutant proteins along with sequence, structure, function and literature information. The analysis of ΔG values of protein structures along with the contribution of free energies showed that the stability is mainly achieved by hydrophobic interactions by overcoming the entropic factors whereas other interactions help to maintain stability, provide the shape and keep the folded state from falling apart.

Stability of Thermophilic Proteins

Thermophilic proteins maintain their stability at high temperatures (80–100°C) and there is a direct relationship between environmental growth temperature and melting temperature ([Gromiha *et al.*, 1999b](#); [Gaucher *et al.*, 2008](#)). Analysis of amino acid sequences in thermophilic proteins as well as their mesophilic homologues showed a preference of Ala, Thr, Arg and Glu over Gly, Ser, Lys and Asp, respectively ([Gromiha and Suresh, 2008](#)). Additionally, the role of specific amino acid properties such as shape,

Gibbs free energy change of hydration in native proteins, dipeptide composition, contacts between amino acid residues, number of ion pairs, hydrogen bonds, packing and aromatic clusters are reported to be important to enhance the stability of thermophilic proteins (Gromiha *et al.*, 1999b; Pica and Graziano, 2016). On the other hand, available pairs of mesophilic and thermophilic protein structures have been used effectively to detect interactions important for the stability of thermophilic proteins. Gromiha *et al.* (2013) carried out a comprehensive analysis on the influence of all interactions and showed that hydrophobicity is the major factor in the stability of thermophilic proteins followed by ion pairs and hydrogen bonds. The systematic elimination of mesophilic proteins based on surrounding hydrophobicity, interaction energy and ion pairs/hydrogen bonds can be used to identify 95% of the thermophilic proteins correctly.

Stability of Proteins Upon Mutations

The availability of thermodynamic data for proteins and mutants in the ProTherm database prompted researchers to understand the factors influencing the stability of mutants as well as predicting the free energy change upon mutation. It has been shown that buried mutations are influenced mainly by hydrophobicity whereas partially buried and exposed mutants are affected by neighboring and surrounding residues (Gromiha *et al.*, 1999b).

The effect of mutation on free energy change of a protein has been systematically analyzed with the development of torsion and distance potentials and environment dependent substitution tables, amino acid properties and energy based approach. Further, the mutational information as well as amino acid properties have been trained with machine learning techniques for predicting the change in free energy upon mutation. Saraboji *et al.* (2006) proposed an “average assignment method” based on the average free energy change of all possible 380 mutants, which provides first-hand information on the capability of a method for predicting the free energy change upon mutation. Further, several methods were developed to estimate the protein stability changes upon point mutations using sequence/structure information such as PoPMuSiC, CUPSAT, SDM, STRUM etc (Table 1). Recent reviews comprehensively describe the methods and applications for predicting the stability of mutants and their applications (Gromiha and Huang, 2011; Gromiha *et al.*, 2016).

Protein Interactions

The interactions of proteins with other molecules govern various cellular processes. The functions of protein complexes have been studied with a view to understand the recognition mechanism, predicting the binding partners and binding site residues as well as the binding affinity of protein-protein, protein-nucleic acid and protein-ligand complexes.

Protein-Protein Interactions

Protein-protein interactions have been studied with two major aspects, (i) within protein-protein complexes and (ii) large scale analysis on protein-protein interaction networks. Protein-protein complex level approach includes the analysis and identification of binding sites, development of structural, functional, thermodynamic and kinetic databases for protein-protein complexes, understanding the binding affinity and recognition mechanism of protein-protein complexes. Interaction network analysis deals with the interaction of each protein with other proteins within the same organism or between different organisms (E.g. host-pathogen interactions) and the complexity of interactions among a set of proteins.

Several databases have been developed to relate various aspects of protein-protein interactions such as interacting pairs of proteins (DIP; Xenarios *et al.*, 2002, IntAct; Orchard *et al.*, 2014), functional interactions between proteins (MINT; Zanzoni *et al.*, 2002), interactions between proteins in human proteome and other organisms (BioGRID; Chatr-Aryamontri *et al.*, 2017), kinetic data on binding affinity (SKEMPI; Moal and Fernández-Recio, 2012) and thermodynamic data for protein-protein interactions and mutants (PROXIMATE; Jemimah *et al.*, 2017) (Table 1). The 3D structures of protein-protein complexes are deposited in Protein Data Bank (Burley *et al.*, 2017).

The availability of experimental data on protein-protein complexes in several databases as well literature prompted researchers to understand the recognition mechanism using statistical analysis of binding sites, identification of binding site residues, prediction of protein-protein complex structures as demonstrated with Critical Assessment of Protein-protein Interactions (CAPRI; Lensink *et al.*, 2017), distinguishing high and low affinity complexes, predicting the binding affinity of protein-protein complexes using sequence and structure based parameters and energy based approach for understanding the recognition mechanism. Recently, Kulandaisamy *et al.* (2017) dissected the important residues, which are involved in both folding and binding, and revealed the characteristic features of these residues. The developments on binding site prediction, binding affinity, complex structure prediction and scoring schemes have been reviewed in detail (Gromiha and Yugandhar, 2017; Gromiha *et al.*, 2017).

Protein-Nucleic Acid Interactions

Owing to the importance of protein-DNA interactions in gene regulation, DNA replication and repair, several computational studies have been performed to understand the recognition mechanism (Gromiha and Nagarajan, 2013). Databases have been developed to accumulate the experimental structures of protein-nucleic acid complexes (NDB) (Narayanan *et al.*, 2013), pairs of contacting amino acid residues and DNA bases (PDIdb) (Norambuena and Melo, 2010), and thermodynamic data of protein-

nucleic acid interactions (ProNIT) (Kumar *et al.*, 2006) (Table 1). Utilizing these information, computational analyses have been carried out to extract important interactions, such as hydrogen bonds, physicochemical properties at the interface, interface surface area, structure based potentials, cation- π interactions, moments of electric charge distribution, DNA stiffness, clustering of protein-DNA complexes and thermodynamics for binding. Further, the role of direct and indirect readout mechanisms (Gromiha *et al.*, 2004) and the importance of scoring functions have been explored for understanding the recognition mechanism of protein-DNA complexes (Gromiha and Fukui, 2011). On the other hand, several methods have been proposed to discriminate DNA binding proteins and predicting the binding sites (Gromiha and Nagarajan, 2013). Nagarajan *et al.* (2013) showed that the performance of prediction methods depends on the structure and function of the specific protein and DNA.

Similar to protein-DNA interactions, the structures of protein-RNA complexes have been effectively used to understand the importance of specific interactions in the recognition mechanism and to predict binding sites (Nagarajan and Gromiha, 2014). In addition, Nagarajan *et al.* (2015) utilized statistical analysis and molecular dynamics simulation of the same protein-RNA complex from different organisms and showed that the recognition mechanism is specific to the target organism.

Protein-Carbohydrate and Protein-Ligand Interactions

The availability of data for protein-carbohydrates is relatively limited, compared to protein-protein and protein-nucleic acid complexes. Malik *et al.* (2010) developed the only database for protein-carbohydrate complex structures (PROCARB) (Table 1) and annotated the binding sites. The available 3D structures have been utilized to reveal the important factors and to understand the recognition mechanism of protein-carbohydrate complexes (Gromiha *et al.*, 2014).

Several databases are available for protein-ligand complexes, specifically for binding free energies, structural information, and druggable binding sites in protein structures (sc-PDB) (Kellenberger *et al.*, 2006). Accordingly, several methods have been proposed to predict the ligand binding sites and binding affinity of complexes upon binding (Tsujikawa *et al.*, 2016; Singh *et al.*, 2016; Pai *et al.*, 2017).

Proteins and Drug Design

Proteins, the key functional molecules in all organisms, are one of the major drug targets to combat diseases. Small organic molecules obtained from natural sources or synthesized in the laboratory are used to inhibit the biological activity of enzymes, receptors etc., which are involved in disease processes. When the 3D structure of a target receptor is known, computational methods (*in silico*) such as virtual screening or docking are used to screen a large number of compounds available in chemical databases to identify potential inhibitors. Protein-ligand docking involves different steps such as identifying the active sites, ligand flexibility and interaction energy between ligand and protein. In the absence of 3D structures of target receptors, homology modeling is used to construct a 3D model of the receptor to be used for virtual screening/docking. In recent years, several attempts have been made to identify hit compounds as potential inhibitors to target proteins for addressing various diseases such as dengue, chikungunya, cancer etc. (Anusuya *et al.*, 2016; Akhtar and Jabeen, 2017; Leal *et al.*, 2017; Zou *et al.*, 2017; Ramakrishnan *et al.*, 2017). These compounds are taken further for experimental verifications and drug development. Chiba *et al.* (2015) proposed a contest based approach for identifying potential inhibitors for cYes kinase using *in silico* screening and experimental validations. In protein-ligand docking, two important bottlenecks are conformational sampling and scoring functions. AutoDock and Glide are widely used freely available and commercial docking programs to identify probable drug compounds. Recently, Anusuya *et al.* (2017) reviewed the methods and applications of drug-target interactions.

On the other hand, quantitative structure-activity relationship (QSAR) model(s) are developed for relating the biological activity of compounds such as IC₅₀ (Half maximal inhibitory concentration) and/or EC₅₀ (Half maximal effective concentration) with structure based features of ligands such as hydrophobic, electronic, steric and topological parameters. The structural features of the ligands are combined using multiple regression to relate with experimental activity values. This procedure is widely used to identify hit compounds for several diseases (Kanakaveti *et al.*, 2017). Alternatively, a set of molecules could be analyzed to identify key pharmacophore features, such as hydrogen bond donors, hydrogen bond acceptors, aromatic rings/hydrophobic groups and related with biological activity.

Conclusions and Future Perspectives

The 3D structures of proteins and their complexes have been effectively utilized to derive several structure based parameters and contact potentials. These features have been successfully used to predict protein folding rates, 3D structures of proteins, protein stability, stability upon mutations, binding sites and binding affinity of protein complexes. The refinement of these parameters would improve the prediction performance as well as successful prediction of diverse systems. We have reviewed the methods and applications as well as latest developments on protein folding, stability and interactions. Most of the prediction methods could be refined with larger datasets and effective learning methodologies such as machine learning algorithms and deep learning. In addition, high throughput *in silico* screening of small molecules and next generation sequence analysis would aid the identification of lead compounds for drug discovery.

Biographical Sketch

M. Michael Gromiha received his PhD in Physics from Bharathidasan University, India and served as STA fellow, RIKEN Researcher, Research Scientist and Senior Scientist at Computational Biology Research Center, AIST, Japan till 2010. Currently, he is working as an Associate Professor at Indian Institute of Technology (IIT) Madras, India. His main research interests are structural analysis, prediction, folding and stability of globular and membrane proteins, protein interactions and development of bioinformatics databases and tools. He has published over 200 research articles, 40 reviews, 5 editorials and a book on Protein Bioinformatics: From Sequence to Function by Elsevier/Academic Press. His papers received more than 9000 citations and h-index is 51. He is an Associate Editor of BMC Bioinformatics as well as Editorial Board Member of Scientific Reports, Biology Direct, Journal of Bioinformatics and Computational Biology and Current Computer Aided Drug design. He has received several awards including Oxford University Press Bioinformatics prize, Okawa Science Foundation Research Grant, Young Scientist Travel awards from ISMB, JSPS, AMBO, ICTP etc., Best paper award at ICIC2011, ICTP Associateship award, ICMR International fellowship for Senior Biomedical Scientists, INSA senior scientist award, Best paper award in Bioinformatics by Department of Biotechnology, India, Institute Research and Development Award at IIT Madras and Outstanding Performance award from Initiative for Parallel Bioinformatics (IPAB), Tokyo Institute of Technology, Japan. He is a member of the National Academy of Sciences, India.

R. Nagarajan completed his PhD degree in Computational Biology from Department of Biotechnology, Indian Institute of Technology Madras, India. He is currently working as a Postdoctoral Research Fellow in Vanderbilt Vaccine Center, Vanderbilt University Medical Center, USA. His main research interests are computational analysis of protein–nucleic acid interactions, recognition mechanism, protein aggregation, computational immunology and development of prediction algorithms, web servers and databases. He has 14 publications (including two book chapters) in reputed journals and received more than 100 citations with h-index 6. He has received Research award from IIT Madras, AU-CBT Excellence award from Biotech Research Society of India, Incentive award from DBT, Govt of India and travel awards from International Society of Computational Biology and Asia Pacific Bioinformatics network.

S. Selvaraj received his PhD degree in Biophysics from the University of Madras, Chennai, India. He has worked as a Collaborative Scientist in RIKEN Life Science Centre, Tsukuba, Japan, and later as Assistant Professor in the Department of Bioinformatics, School of Life Sciences, Bharathidasan University, Tiruchirappalli, India. Post-retirement he has been awarded the Emeritus Fellowship by the University Grants Commission, New Delhi, India. He has published about 60 research articles and 6 reviews. His publications have received more than 2000 citations with h-index of 20. He has been awarded the National Associateship by the Department of Biotechnology, Government of India.

Introduction

The Value of Understanding Protein Structure

Our scientific understanding of the molecular basis of life has expanded dramatically since the very first macromolecular structures were determined in late 1950s. These huge achievements in building atomic models of myoglobin (Kendrew *et al.*, 1958) and hemoglobin (Perutz *et al.*, 1960) paved the way for resolving structures of more complex proteins. More recently the structures of enormous complexes such as the ribosome and drug targets such as G protein-coupled receptors have been determined. These highly informative structures have provided answers to the basic understanding of the molecular machinery in many biological processes and have contributed enormously to human health. An early example of drug design informed by knowledge of the target protein structure is that of the carbonic anhydrase inhibitor dorzolamide which was approved in 1995 (Kubinyi, 1999). Several anti-virals directed against HIV protease were designed using mainly structure-based methods (Greer *et al.*, 1994). The 22 Nobel prizes awarded in the field of structural biology between 1946 and 2016 highlight its importance.

While technological advances and talented scientists have been key to these discoveries, no small part has been played by the structural biology community's willingness to make their data, in the form of atomic models, freely available. To enable this, the community has instigated and supported resources which store and distribute these data. Some of these resources archive experimental data and make it available, others take this archive data and classify it according to their own analyses and annotations. This chapter reviews some of these resources, all of which are available online. URLs of those mentioned are given in Table 1.

The Protein Data Bank

The oldest and largest database of protein structure is the Protein Data Bank (PDB) which archives, curates and distributes experimentally determined structural information. Analysis of citations of the PDB archive, and the data it contains indicate how vital this resource is to the biomedical community (Bousfield *et al.*, 2016). In maintaining a centralised, consistent archive of protein structures, the PDB has played a crucial role in the field of structural bioinformatics (Lesk and Chothia, 1980; Chothia and Lesk, 1986).

The PDB is a freely accessible repository for experimentally determined 3D structures of proteins, nucleic acids, and complex assemblies. Many journals now require scientists to have deposited their data with the PDB before a manuscript is accepted for publication. When the PDB was formed as a collaboration between the Brookhaven National Laboratory (BNL) in the US, and the Cambridge Crystallographic Data Center in the UK (Protein Data Bank, 1971), it contained just seven structures. All of these were of proteins and solved by X-ray crystallography. 46 years later, the archive contains more than 130,000 structures of over 40,000 unique macromolecules (see Fig. 1). Methodology too has expanded and the PDB archives structures determined by several experimental techniques. Around 90% of structures in the archive are solved by diffraction techniques with structures solved by nuclear magnetic resonance (NMR) and electron microscopy (EM) making up most of the remaining 10%. Though historically this was not the case, experimental data from which the models are derived must also be deposited to support the atomic coordinates. In the case of diffraction studies, structure factors are deposited to the PDB and for NMR derived models, the PDB archives chemical shifts and geometric restraints. Further NMR data can be archived with the Biological Magnetic Resonance Data Bank (Ulrich *et al.*, 2008). In the case of electron microscopy studies, data are deposited to the Electron Microscopy Data Bank (Tagari *et al.*, 2002).

By 1977 the PDB had added a further distribution center in Japan (Bernstein *et al.*, 1977), and over time multiple sites mirrored PDB data- a common phenomenon in the days of low speed web connections. PDB format data could be deposited either to BNL or the Macromolecular Structure Database (MSD) at the European Bioinformatics Institute (Keller *et al.*, 1998; Sussman *et al.*, 1999). In 1998 the Research Collaboratory for Structural Bioinformatics (RCSB) took over from BNL as the US PDB center. By the turn of the millennium, the Protein Data Bank Japan (PDBj) based at the Institute for Protein Research, Osaka University was also handling deposition of PDB data. In 2002, to recognise the growing international nature of structural biology and its data archiving activities, the Worldwide Protein Data Bank (wwPDB) was formed (Berman *et al.*, 2003). Founder members were RCSB, MSD (now Protein Data Bank in Europe (PDBe)) and PDBj. In 2008, Biological Magnetic resonance Bank (BMRB (Markley *et al.*, 2008)) which deals specifically with NMR data, became a wwPDB partner. The history of the PDB and wwPDB is well documented elsewhere (Berman *et al.*, 2016; Berman *et al.*, 2014; Berman *et al.*, 2012; Meyer, 1997). The wwPDB manages the PDB archive and ensures that the PDB is freely and publicly available to the global community, conforming to the FAIR (Findable, Accessible, Interoperable, and Re-usable) guiding principles (Wilkinson *et al.*, 2016).

Depositing data

Since 2014, data has been deposited to the wwPDB via a unified deposition interface across all wwPDB sites. This system, OneDep (Young *et al.*, 2017), directs data depositions to the relevant wwPDB partner site for processing based on geography. Thus RCSB

PDB handle data from the Americas and Oceania, PDBj process data from Asia and PDBe annotate all data from Europe and Africa. NMR data not linked to a PDB structure deposition or additional experimental data (e.g., free induction decay) can be deposited directly to BMRB.

Once deposited, data can be held privately for up to one year and are usually released on publication of the accompanying paper. the PDB archive is updated weekly at 00.00 UTC each Wednesday and the complete updated archive is available from the master FTP site (see Relevant Websites section) or from any of the wwPDB partners.

Fig. 1 Growth of the PDB archive over time. The green bars show total number of PDB entries and the red line unique macromolecules (as determined by standardised molecule names).

Curation and validation

Atomic coordinates merely define the shape of a molecule. To make the structure data truly useful, they must be related to other information (Gerstein, 2000). Thus structures are almost always accompanied by a host of metadata. In the PDB archive, these are either entered by the scientists solving the structure, or added by the curation procedures of wwPDB (Dutta *et al.*, 2008; Sen *et al.*, 2014). These annotations include details of the experiment performed to produce the model, cross references to polymer sequence databases, and any discrepancies between the polymer sequences in the model and in a reference database. Where a structure is described in a scientific paper, the citation is included.

Curation also includes adding information about the quaternary structure of the entry. The convention in crystallography is to deposit only the smallest repeating unit of the crystal to the PDB (the asymmetric unit, ASU) thus the true quaternary structure may contain only a part of the ASU or consist of multiple ASUs.

There is frequently a misconception that the atomic coordinates define the absolute positions of all the atoms in a given macromolecule. It should be remembered however that the coordinates are a model which is an interpretation of experimental data. Some data may enable a more precise model to be built than other data. Users of structural databases need to be aware of the limitations of the model when drawing conclusions from it. To address this issue, wwPDB convened expert task forces representing the structural biology community which published their recommendations on how the wwPDB should assess the quality of structures in the PDB (Read *et al.*, 2011; Henderson *et al.*, 2012; Montelione *et al.*, 2013; Adams *et al.*, 2016). Following these recommendations, extensive validation reports now accompany the structures in the PDB archive.

File formats

Early in the history of structural biology, as the possibility of viewing atomic coordinates on a computer rather than as a physical model became reality, the community realised that standards were needed if structure data were to be read computationally between different research groups. Thus the PDB file format was introduced using the 80-column Hollerith card format.

The PDB format defined the standard for representation of atomic coordinates in structural biology for decades and as a human readable text file, is still used by many today. The historical fixed width of the PDB format fields imposes severe limitations for modern structural biology and in 2014 the wwPDB officially moved to use PDBx/mmCIF (Bourne *et al.*, 1997; Westbrook and Bourne, 2000) as the master format for the PDB archive. This format is free of the limitations inherent in the PDB format and is much more extensible to record the diverse metadata which accompanies modern coordinate data.

PDB data is also distributed by the wwPDB in PDBML format (Westbrook *et al.*, 2005), which is an XML-like format, and as RDF format. Both of these are direct translations of the PDBx/mmCIF formatted files.

Access to PDB Data

Websites of wwPDB Members

“The PDB” refers to the FTP archive of files distributed by the wwPDB partners. While the wwPDB website provides details of archive policies and procedures, it is the wwPDB partners who provide tools to search, download, visualize, and analyse protein structures and annotations from the archive. Data from each entry are presented on a series of pages which have been termed

'atlases' detailing the structure and its annotations. Whilst hosting identical data, each site develops its own website, providing unique views of the primary data, and a variety of tools and resources to analyse that data. All sites also have RESTful API calls which grant programmatic access to the archive. A brief summary of the wwPDB partner sites is given below.

Protein Data Bank in Europe

The Protein Data Bank in Europe (PDBe) (Velankar *et al.*, 2016) is an interactive and image-rich site providing access to all data in the PDB archive via a faceted search system. Search results can be ranked based on a series of metrics including the quality of structures. Each entry is detailed on its own series of pages on which macromolecules can be viewed in three dimensions using the in-browser viewer LiteMol. Visualisation of electron density maps for X-ray structures and electric potential maps for those derived by electron microscopy is possible via this viewer. Annotations such as sequence and structure domains, and validation data can be displayed on the model in this viewer and also on sequence and topology views, which are all interlinked (see Fig. 2).

PDBe works with Europe PMC to list publications which cite the paper describing a particular structure, as well as those which mention the PDB code but do not cite the paper.

Advanced tools to analyse the data include PDBePISA (Krissinel and Henrick, 2007), which assesses stability of interactions within a crystal structure, and PDBeFold (Krissinel and Henrick, 2004), which is used to search for structures of a similar three dimensional topology.

Structure integration with function, taxonomy and sequence (SIFTS)

PDBe, along with UniProt (The UniProt Consortium, 2017) produces the SIFTS resource (Velankar *et al.*, 2013) which maintains up-to-date cross-references between the UniProt sequence database and the sample sequence in the PDB entry. Through mapping

Fig. 2 1D, 2D and 3D interactive views of a HIV protease (PDB entry 2az9) on the PDBe website. The topology diagram and 3D structure are shown coloured by model geometry quality according to the wwPDB validation report and electron density is displayed.

to UniProt the SIFTS service adds cross references to Gene Ontology (GO) (Jones *et al.*, 2014; Ashburner *et al.*, 2000) terms, to sequence motifs from InterPro (Jones *et al.*, 2014), and Pfam sequence domains (Finn *et al.*, 2016). SIFTS also collates cross references to structural domains (SCOP, CATH). This service is used by the other wwPDB partners to maintain up-to date cross-references.

The Protein Data Bank Japan

The Protein Data Bank Japan (PDBj) (Kinjo *et al.*, 2017) provides search, advanced search and visualisation facilities for all entries in the PDB, not only in English but also in Japanese, Chinese and Korean. On each entry page, structures can be viewed in 3D in a variety of molecular viewers. The layout of the PDBj site is user-configurable and all PDB entries are provided in Resource Description Framework (RDF) format.

A variety of advanced services are supplied by PDBj including calculations of electrostatic surfaces and eF-seek, which searches protein structures for similar binding sites. GIRAF (Kinjo and Nakamura, 2007) finds similarities in small molecule binding sites between proteins which might lack detectable sequence similarity. Omokage is a PDBj service which finds structures of similar shapes across PDB and EMDB archives (Suzuki *et al.*, 2016).

Research Collaboratory for Structural Bioinformatics PDB

The Research Collaboratory for Structural Bioinformatics (RCSB) PDB website (Berman *et al.*, 2002) also has a search, advanced search, and pages for each structure in the PDB archive. Search results can be saved in customisable reports. Each PDB entry has a summary page (see Fig. 3) with data described across a series of subpages which tabulate data and annotations, including sequence and structure similarity with other molecules in the PDB archive. Structures can be viewed in 3D using the online NGL viewer (Rose and Hildebrand, 2015) and various other visualisation programs. Recent updates have included linking to other databases

and mapping human proteins to their locations on the genome (Rose *et al.*, 2017). Mentions of the PDB code in pubmed are plotted per year.

RCSB enables pairwise structure and sequence alignments using a variety of different algorithms.

Statistics of the PDB archive are readily available at RCSB displayed as interactive graphs across a wide range of data criteria.

In common with its partner sites, RCSB has the facility to search the PDB archive for small molecules which are bound to macromolecules.

Biological Magnetic Resonance Data Bank (BMRB)

The Biological Magnetic Resonance Data Bank (Ulrich *et al.*, 2008) collects and distributes data from nuclear magnetic resonance experiments on proteins and other biological molecules. In addition to the atomic model and data directly used to derive it, BMRB serves as a repository for other kinds of NMR experimental data, such as kinetic and NMR relaxation parameters, and free induction decay (FID) data. BMRB webpages for NMR derived protein structures display validation data and links to the experimental data in addition to the model. BMRB has mirror sites in Osaka and Florence in addition to the master site in Wisconsin.

Protein Structure Databases outside of the wwPDB

In addition to members of the wwPDB consortium, several other databases archive protein structural models and/or the experimental data used to derive them. Some of these are listed below.

Electron Microscopy Data Bank

The Electron Microscopy Data Bank (EMDB) is a repository for three dimensional volumes of macromolecular complexes and subcellular structures derived by electron microscopy. It was founded by the MSD team (now PDBe) at EBI in 2002 (Tagari *et al.*, 2002). EMDB archives data from a range of electron microscopic techniques including single-particle reconstruction, tomography, and electron crystallography. The scale of data in the EMDB archive ranges from tomography of whole cells, to electron crystallographic studies of peptides at atomic resolution. In the last few years, improvements in instrumentation and software have been enormously beneficial to the field. These advances, termed the ‘resolution revolution’ (Kühlbrandt, 2014) have resulted in a huge increase in both the quantity of data in EMDB and its quality, certainly in terms of resolution (Patwardhan, 2017).

EMDataBank, a collaboration between PDBe at EMBL-EBI, the RCSB PDB and the National Center for Macromolecular Imaging (NCMI) (Lawson *et al.*, 2011), has pushed forward data standards in the EM community. Outcomes have included EMDB files being archived jointly in the wwPDB FTP archive, electron microscopy validation reports and the integration of EM deposition with the wwPDB deposition system allowing simultaneous deposition of EM maps to EMDB and the fitted model to PDB. EMDB has a weekly release cycle, synchronized with that of the wwPDB.

Accessing EMDB data

Whilst not formally a wwPDB partner, the data in EMDB archive is available in the wwPDB FTP tree and it can be further accessed through four websites: the EMDB pages at EMBL-EBI, at the RCSB PDB website, PDBj and via the emdatabank.org website. Each website presents the data in different ways. A summary is provided below.

EMDB at EBI provides an advanced search, with EM maps available for download or viewable online using a number of tools and viewers. Many of these visualisation tools also serve as validation tools. In the visual analysis page (Lagerstedt *et al.*, 2013), the map data is presented to the user as a surface, projection, slices and overlaid with the fitted model. The volume slicer tool (Salavert-Torres *et al.*, 2016) is of particular use when visualising tomogram volumes and allows navigation through the slices of a tomogram. Statistics for the EMDB archive are provided in live graphs.

PDBj also provides a search functionality (including shape recognition) and access to EMDB data through the EM Navigator which also provides visual analysis and validation tools. Maps can be viewed as images and movies from UCSF Chimera (Pettersen *et al.*, 2004), the session files for which are available for download. The Yorodumi viewer allows interactive viewing of the map and the PDB model. To analyse overall trends of the data in the EMDB archive an interactive statistics table is provided. The RCSB PDB provide a basic search tool, links to download and view the data in the EMDB.

The EMDataBank site provides an access point for both deposition to and retrieval of data from the EMDB archive in addition to the derived models in the PDB. It also provides data for various ‘challenges’ which are helping drive developments in the electron microscopy field.

Solution Scattering Databases

X-ray and neutron scattering techniques can provide data on the size and molecular envelope (i.e., shape) of a macromolecule. Small Angle Scattering Biological Databank (SASBDB) (Valentini *et al.*, 2015) and BIOISIS (Hura *et al.*, 2009) are repositories of structural information from these experimental techniques. They allow researchers to deposit and access experimental scattering

data and derived models from the scattering experiment. Both provide experimental and derived information and other relevant manually curated data such as experimental conditions, sample details and structural models that have been provided by the depositor during the time of data deposition.

Hybrid and Integrative Techniques

With the advancement of scientific methods, researchers working on challenging biological systems are now able to use a whole suite of different experimental techniques, sometimes supplemented by theoretical data, to determine three dimensional structures of proteins and large complexes. Such approaches are referred to as integrative or hybrid methods (Sali *et al.*, 2015). For instance, mass spectrometry and cross linking data can give insights into a protein's fold or the composition of a protein-protein complex. PRIDE at EBI (Vizcaíno *et al.*, 2016) archives such mass spectrometry data. More generally, where such data should be archived, and vitally, how they should be validated, remains a challenge for the scientific community.

Modelling Archives

On the advice of the community, from 2006 the wwPDB ceased accepting structures determined *in silico* (i.e., by homology or *ab initio* methods) (Berman *et al.*, 2007) and such models which were in the PDB archive were removed. Nevertheless, homology modelling and protein structure prediction is a critical area of research in structural biology with competitions such as CASP (Kryshtafovych *et al.*, 2014) and CAPRI (Lensink *et al.*, 2016) assessing structure prediction and docking methodologies. There is therefore a community demand to store the information collected from theoretical protein modelling.

SWISS-MODEL Repository

The SWISS-MODEL repository (Bienert *et al.*, 2017) is a database of annotated 3D protein structure models generated by the SWISS-MODEL homology-modelling pipeline. Currently the repository contains models for protein sequences in the UniProt database as well as experimentally determined structures from PDB with mapping to UniProt. If a particular protein is absent from the repository, users have the option to attempt building the model. Model quality is indicated over a variety of validation criteria.

Protein Model Portal

Protein Model Portal (Haas *et al.*, 2013) provides access to experimentally determined protein structures and also theoretical models based on sequences available in UniProt. Currently, over 5 million sequences are covered by a model. Crucially, the service also gives an indication of the quality of the model.

Other services exist which will generate a protein model based on homology, for example I-TASSER (Yang *et al.*, 2015) and Phyre2 (Yang *et al.*, 2015; Kelley *et al.*, 2015), but unlike the SWISS-MODEL repository these lack archives of previously calculated structures.

'Derived' Protein Structure Databases

A plethora of specialist databases exist which do not archive structures, but take data from the PDB archive and provide further manual or computational analysis of the data. Some use the whole PDB archive, whilst others might focus on specific protein families. Approximately 25% of resources described in the Nucleic Acids Research database issue each year make use of PDB data in some way. An extensive list of protein structure databases is available online at the Nucleic Acids Research website (see Relevant Websites section).

Here we will detail just a few of these as space allows. For the sake of clarity, we have divided these databases into different types.

- (1) Secondary protein structure atlases
- (2) Fold classification databases
- (3) Subject-specific resources

Secondary Protein Structure Atlases

Several resources integrate information from other resources with three dimensional protein structures and provide a wealth of information to the research community. Some could be considered 'atlases' providing individual webpages for each structure in the PDB archive. Often these were created to provide functionality which wwPDB partner sites lacked, but in many cases, this functionality is now present at one or more of the wwPDB partners. While the members of the wwPDB consortium release new data each Wednesday, other sites necessarily do not have access to these data prior to release and will clearly lag behind the wwPDB partners' sites.

PDBsum

PDBsum (Laskowski *et al.*, 1997) is a pictorial database that provides an overview of the contents of each entry in the PDB archive. It provides several tools to analyse three dimensional macromolecular structures. PDBsum's Ligplot tool gives a pictorial description of a ligand binding site while Nucplot displays interactions between proteins and nucleic acids, and the Prot-prot tool generates a schematic diagram of protein-protein interfaces.

OCA

OCA displays information from the PDB archive and integrates data from several other sources. Its front page is an advanced search form for users to generate specific search queries. Unusually for protein structure databases, the pages for PDB entries in OCA are image free.

Proteopedia

Proteopedia (Hodis *et al.*, 2010) is a wiki-based encyclopedia of macromolecular structures in which annotations are community sourced. Thus the content of each page is extremely variable. Each page has a 3D structure visualiser adjacent to user-editable text describing the structure. The 3D views are scriptable such that users can illustrate a text description with specific views in 3D. Proteopedia has pages that describe generic molecules and complexes in addition to pages for specific PDB entries.

Jenalib

Jenalib (Reichert and Sühnel, 2002) has an emphasis on visualisation and analysis of all entries from the PDB. It provides tools such as SiteDB, GO2PDB and HeteroDB, which are useful to find information on ligand binding sites, Gene ontology and bound small molecules, respectively.

Molecular modelling database

Molecular modelling database, MMDB (Madej *et al.*, 2014) contains experimental structures derived from PDB. MMDB links proteins of similar sequence and structure and displays information about bound small molecules. It allows users to analyse the macromolecular structure in an interactive 3D manner.

Fold Classification Databases

It was recognised relatively early in the history of structural biology that structure is better conserved than sequence (Rao and Rossmann, 1973; Chothia and Lesk, 1986). Several resources classify proteins by their three dimensional fold and, through fold similarity, help infer evolutionary and functional relationships.

SCOP

Structural Classification of Proteins (SCOP) (Murzin *et al.*, 1995) is a database which classifies protein domains according to regions of structural similarity, utilizing both manual and automatic curation. This database uses known structures from the PDB to classify protein folds hierarchically, based on structural and evolutionary relationships. Users can identify known protein folds within their structure of interest and use this information to suggest potential functions of the protein.

More recently, SCOP2 (Andreeva *et al.*, 2014) was launched which presents structural relationships as a network, rather than a tree-like hierarchy. While it is currently a prototype version, SCOP2 enables more complex representations of the relationships between different folds than was possible in the original SCOP. The SCOPextended (SCOPE) database (Chandonia *et al.*, 2017) adds many more structures from the PDB archive to the original SCOP classification.

CATH

The CATH database (Sillitoe *et al.*, 2015) also classifies protein folds. It is named according to the hierarchy used in classification: Class, Architecture, Topography and Homology. Philosophically, CATH and SCOP are very similar, differing in precisely what folds and domains of proteins are identified. CATH also links with Gene3D (Lam *et al.*, 2016) to extend this classification to protein sequences for which a 3D structure is not yet available but can be predicted. In addition to browsing the CATH database, CATH's web pages allow searches based on an uploaded sequence or coordinate file.

ECOD

Both SCOP and CATH databases require manual curation and neither of the two databases has kept up to date with releases in the PDB (though recent developments are addressing this). A further fold classification methodology, Evolutionary Classification of Protein Domains (ECOD) (Cheng *et al.*, 2014; Schaeffer *et al.*, 2017) aims to overcome this problem by offering only automatic annotation of structural domains. ECOD also allows users to upload their own coordinate file for fold classification.

ArchDB

CATH and SCOP classify folds based on the secondary structure elements within a protein, but ArchDB (Bonet *et al.*, 2014) curates instead those non-regular portions of a protein, termed loops, which still have defined structures. Loops are classified on their

geometry into 10 separate types. The interface allows users to find structures of loops based on geometry and classification and to search the database using a variety of other criteria.

Subject-Specific Resources

There are many resources that provide functional annotation for specific types of proteins, dependant on the interests of the creators. The following descriptions provide just a taste of what is available, many are the work of individual labs and their longevity is not guaranteed.

VIPERdb (Carrillo-Tripp *et al.*, 2009) focusses on capsid structures from icosahedral viruses. VIPERdb also provides data on computational analyses on icosahedral virus systems. GPCRdb (Isberg *et al.*, 2017) provides annotations and tools focussing on G-protein coupled receptors.

PyIgClassify (Adolf-Bryfogle *et al.*, 2015) and SAbDab (Dunbar *et al.*, 2014) provide extra annotation on antibodies, SpliProt3D (Korneta *et al.*, 2012) brings together structures and models of the human spliceosome components.

The structures of membrane proteins are also notoriously difficult to solve experimentally but of great biological relevance. Several resources focus on membrane proteins. Among these resources are PDBTM (Kozma *et al.*, 2013) which takes proteins from the PDB with likely membrane spanning regions, classifies them and indicates the probable membrane embedded region. The Membrane Protein Data Bank, MPDB (Raman *et al.*, 2006), MemPROT and “Membrane Proteins of known structure” also list transmembrane structures from the PDB.

Rather than subject specificity, Indian PDB provides a database of structures solved by Indian structural biologists, sorted by institute.

Integrating Structure into the Bigger Picture

Protein structures do not exist without a context, and many databases are integrating structures into their resources or ensuring that they link to relevant structural resources. Thus biologists searching for data relevant to their field of research may encounter protein structure outside of the specialist protein structure databases. A few are mentioned below.

COSMIC 3D

COSMIC 3D maps cancer mutation data from COSMIC (Forbes *et al.*, 2017), a database of somatic mutations in cancer, to three dimensional protein structures, allowing users to visualize the location of these mutations in the three dimensional structure.

EBI search

Whilst all of the data resources at the European Bioinformatics Institute have their own search systems, the EBI-wide search engine provides a facility to search all of these resources, highlighting the interconnectivity of biological data resources. In a similar way, searches at NCBI (NCBI Resource Coordinators, 2016) integrate MMDB, which is a secondary atlas for the PDB (Park *et al.*, 2017).

Open Targets

Open Targets (Koscielny *et al.*, 2017) is a platform which brings together data from a variety of different biomedical data resources, including structure data, with the aim of aiding its user community in identification of potential drug targets.

Genome3D

Genome3D (Lewis *et al.*, 2015) integrates a variety of resources of fold classification and structure prediction to extend structural annotation across the genomes of several model organisms.

Challenges for the Future

Technological advances in crystallography, not least robotics enabling high throughput, microfocus beamlines, free electron lasers and the amazing progress in electron microscopy are resulting in a huge leap in the volume of protein structure data. As mentioned above, integrative and hybrid techniques combine very diverse types of data.

Advances in speed and reduction in cost of genome sequence have resulted in sequences of many related proteins being easily available. New modelling techniques based on the sequence comparisons can predict even novel protein folds (Ovchinnikov *et al.*, 2017).

With such an avalanche of data, protein structure databases have an exciting challenge going forward in archiving these data. They need to be made available in a meaningful way such that specialists and non-specialists alike can locate the data they need and draw relevant conclusions from it.

Acknowledgements

We thank EMBL and the Wellcome Trust for funding and Drs Aleksandras Gutmanas and Sameer Velankar for critical feedback on the manuscript.

Protein Structure Classification

Natalie L Dawson, Sayoni Das, Jonathan G Lees, and Christine Orengo, Institute of Structural and Molecular Biology, University College London, London, United Kingdom

Introduction to Protein Structure Classifications

The first three-dimensional protein structure, myoglobin, was solved by X-ray crystallography in the late 1950s. The number of solved protein structures grew at a steady rate and a computational archive was built in 1971 to collect, standardise and distribute this data. This archive, known as the Protein Data Bank (PDB) has been growing at an exponential rate since the mid 1990s, increasing from 3000 structures to 135,000 entries in November 2017. The dramatic increase in the data made many manual analyses impractical. Organising the data into structural and evolutionary classifications, gave biologists insights into common structural units and evolutionary relationships.

Several publicly available, structural classifications have been developed providing information on fold groups, evolutionary relationships and sequence families (see [Table 1](#)). These include: SCOP ([Hubbard *et al.*, 1997](#)), SCOP2 ([Andreeva *et al.*, 2014](#)), CATH ([Orengo *et al.*, 1997](#); [Dawson *et al.*, 2017](#)), ECOD ([Cheng *et al.*, 2014](#)), and HOMSTRAD ([Mizuguchi *et al.*, 1998](#)). These classifications are built on a combination of sequence and structure comparison methods (e.g., SSAP ([Taylor and Orengo, 1989](#)), Dali ([Holm and Sander, 1995](#)), SSM ([Krissinel and Henrick, 2004](#)), and CE ([Shindyalov and Bourne, 2001](#))).

There are also a number of structural comparison web servers that provide lists of structural neighbours, including: the protein structure comparison service, PDBFold at the European Bioinformatics Institute ([Krissinel and Henrick, 2004](#)); VAST at the NCBI ([Madej *et al.*, 1995](#); [Gibrat *et al.*, 1996](#)); Combinatorial Extension (CE) ([Shindyalov and Bourne, 2001](#)) at the RCSB Protein Data Bank; Dali ([Holm and Sander, 1995](#)) at the University of Helsinki.

Table 1 Protein structure classifications and nearest-neighbour resources

Acronym/Name	Description	URL
RCSB PDB Protein Comparison Tool	The Combinatorial Extension method is integrated into the RCSB PDB to compare pairs of protein structures. It compares a structure with the PDB and identifies its nearest neighbours. The RCSB PDB protein comparison tool provides access to CE to perform pairwise structural alignments.	http://www.rcsb.org/pdb/workbench/workbench.do
CATH	CATH assigns protein domain structures into a structural classification hierarchy: Class, Architecture, Topology (fold), Homologous superfamily. A mixture of automated and manual curated steps are used in its continual development.	http://cathdb.info/
Dali server	The Dali server allows users to perform structural comparisons for: one structure against the whole PDB; one structure against user-defined list of PDBs; a list of structures to get an all-against-all comparison.	http://ekhidna2.biocenter.helsinki.fi/dali/
ECOD	Evolutionary Classification of Domains. The classification consists of proteins with experimentally-determined 3D structures and focuses on establishing remote evolutionary relationships.	http://prodata.swmed.edu/ecod/
HOMSTRAD	HOMologous STRucture Alignment Database. Comprises protein structural alignments for homologous families.	http://mizuguchilab.org/homstrad/
PDBeFOLD	Uses the Secondary Structure Matching (SSM) algorithm to compare a given structure with the whole PDB archive, and identifies the nearest structural neighbours.	http://www.ebi.ac.uk/msd-srv/ssm/
SCOP	Structural Classification of Proteins. Classifies protein domains into a hierarchy consisting of: class, fold, superfamily and family.	http://scop.mrc-lmb.cam.ac.uk/scop/
SCOP2	Structural Classification of Proteins 2. A prototype successor of SCOP, which uses a directed acyclic graph to describe complex structural and evolutionary relationships. Each graph node represents a particular type of relationship.	http://scop2.mrc-lmb.cam.ac.uk/
VAST	Vector Alignment Search Tool. Identifies 3D domains for a given query and then finds a list of nearest structural neighbours within the Molecular Modelling Database (MMDB).	https://www.ncbi.nlm.nih.gov/Structure/VAST/vast.shtml
VAST +	Vector Alignment Search Tool Plus. Uses all the domains identified by VAST for a query structure, then finds macromolecular structures that have a structurally similar biological unit. This differs from VAST, which focuses on individual protein molecules (e.g., domains).	https://www.ncbi.nlm.nih.gov/Structure/vastplus/vastplus.cgi

Modified from Pearl, F.M.G., Sillitoe, I., Orengo, C.A., 2015. Protein Structure Classification. eLS, pp. 1–10.

Fig. 1 Figure showing how automatic detection of domains can be non-trivial for multi-domain proteins. (A) The 3D structure of the PDB 5F3Y, chain A. The domain chopping proposed by the method ChopClose is shown, where each colour represents a different domain. (B) The proposed domain choppings by the different algorithms used to identify domains for classification in CATH. The different colours represent different domains proposed by each method, as in (A). See descriptions of the methods below. The chain start (972) and stop (1559) PDB residue labels are shown at the bottom of the figure. The domains have been numbered where space permits.

Protein Domains and Methods Used to Identify Them

Early analysis of protein structures revealed that proteins can have one or more distinct structural units, or domains. A structural domain is created by the protein polypeptide chain folding into a compact unit with its own hydrophobic core. Domains consist of secondary structures (e.g., alpha helices and beta strands) and supersecondary structures (i.e., any structural motif, e.g., helix-turn-helix, beta hairpin, alpha-beta motif), and have an average size of 150 ± 50 residues (see [Pearl et al., 2015](#) for a review). They are typically formed of contiguous parts of the polypeptide chain but may be formed of discontinuous sections. Domains can be defined as semi-independently evolving units, and sometimes have their own independent functions ([Hadley and Jones, 1999](#)).

The multi-domain architecture (MDA) of a protein describes the sequential order of domains within the protein polypeptide chain. Studies have found that over two-thirds of known prokaryotic proteins, and almost 80% of eukaryotic proteins, contain at least two domains ([Teichmann et al., 1998](#); [Gerstein, 1998](#)). Domains within multi-domain proteins can be difficult to identify if they have extensive contacts between them, making it hard to recognise boundaries between the domains. [Fig. 1](#) illustrates the difficulties of identifying domain boundaries in a multi-domain protein when the methods aiding manual curation disagree with each other (see subsequent sections for details on these algorithms). The curator uses these results, and the literature, to decide on the correct domain boundaries.

Although the protein domain structure data is still increasing at an exponential rate, the number of new folds discovered has plateaued in recent years, indicating that existing fold libraries cover the majority of structural space. The comprehensive fold libraries now available can be searched with newly solved structures, using structure based algorithms, to find related domain folds and inherit the domain boundaries (see Section Sequence-based methods for recognising domains in proteins). Protein sequence data, i.e., for domains of known and predicted domain structure, is also very comprehensive and can be searched with powerful HMM-based algorithms to find domain matches and inherit boundaries (see Section Structure-based methods for recognising domains in proteins). CATH and ECOD use their own automated protocols for domain assignment, based on structure- and sequence-based algorithms. In addition, CATH uses a selection of *ab initio* algorithms, which are used to detect domains with novel, uncharacterised folds (see Section *Ab-initio* methods for recognising domains in proteins). These different types of algorithms are described below.

Algorithms to identify protein structural domains

Structure-based methods for recognising domains in proteins

To identify protein structural domains for the CATH resource, the ChopClose automated protocol ([Greene et al., 2007](#)) is first used to scan newly determined protein structures from the PDB against the structures of multidomain proteins in CATH, that have

PDB search results [Job: #12845]

Query Structure

CATH Version 4.1
Algorithm CATHEDRAL
Library CATH_S35

CATHEDRAL found 82 matching structures in CATH (v4.1)

Fig. 2 Results from running a structure-based search with the CATHEDRAL web server using an example case PDB 4RGH, downloaded from the PDB. A total of 82 matching structures were found in CATH with the most confident domain matches shown in green, through to the least confident matches in red.

already had their domain boundaries identified. For query structures that have high structure similarity to multi-domain structures already classified in CATH (a score ≥ 80 by the SSAP algorithm (range 0–100) (Taylor and Orengo, 1989), $\text{RMSD} \leq 6\text{Å}$) the domain boundaries from the match are inherited to the query.

If there is no significant match, the chain is submitted to a number of additional algorithms (structure-based: CATHEDRAL, sequence-based: CATH-HMMscan) to propose domain boundaries (see Sections “Sequence-based methods for recognising domains in proteins”, “Ab-initio methods for recognising domains in proteins”, “Hierarchical Structural Classification”, “Class”, “Architecture”, “Topology or fold similarity”, “Homologous superfamily”, “Homologous family”, “Nearest-Neighbour Clustering”, “Integration of the SCOP And CATH Resources”, “Current Status of the Protein Structural Universe”, “Structural Families in the Genomic Era”). The CATHEDRAL algorithm (Redfern *et al.*, 2007) is used to perform a structure-based search of a query chain against a library of previously classified protein domains in CATH. First, an initial fast secondary structure comparison is run between structures using graph theory to find putative fold matches. These putative-fold-matching domains are realigned to the query with the slower, more accurate SSAP to produce a structural alignment, from which the domain boundaries can be inferred. High scoring matches (i.e., SSAP score ≥ 80 and $\text{RMSD} \leq 6\text{Å}$) provide confidence to infer the domain boundaries of the match (see Fig. 2).

In ECOD, query protein structures from the PDB are first scanned against protein chains and domains in ECOD fast sequence based approaches (see below). If the sequence-based methods do not return any significant match, the query chain is searched against a library of representative domain structures in ECOD using a DaliLite search (Holm and Park, 2000). The domain boundaries are inherited if there is significant structural similarity and an acceptable BLOSUM-based alignment score (Cheng *et al.*, 2014). If this does not return any results, the chain is marked for manual curation.

Table 2 Algorithms used in the CATH Update protocol to automatically identify protein domains. The best result from each algorithm is also provided to the CATH curators for manual curation purposes

Acronym/Name	Description	Reference
ChopClose	Compares query chains against previously chopped chains in CATH to find the best match.	Greene <i>et al.</i> (2007)
CATHEDRAL	CATH's Existing Domain Recognition ALgorithm. Uses GRATH to find the best fold match and then SSAP to produce an accurate structural alignment of these fold matches. Publically available to use through: http://cathdb.info/search/by_structure	Redfern <i>et al.</i> (2007)
HMMs	Hidden Markov Models. Probabilistic models are created from multiple sequence alignments to capture information on the amino acid probabilities at each alignment position. Protein sequences are searched against these models to identify homology and to aid the inference of domain boundaries.	Karplus <i>et al.</i> (1998)
DETECTIVE	<i>Ab initio</i> algorithm that identifies protein domains by searching for the hydrophobic core and residues in contact with the core.	Swindells (1995)
DOMAK	DOmain MAKer. <i>Ab initio</i> algorithm that splits a given protein into arbitrary pieces (i.e. domains) until it has found the pieces that maximise intra-domain contacts and minimise inter-domain contacts.	Siddiqui and Barton (1995); Holm and Sander (1994)
PUU	<i>Ab initio</i> algorithm that studies the motion of residue clusters to analyse how different parts of the protein move in relation to each other. Each domain in a multi-domain protein has its own continuous, relative motion, which is used to identify domain boundaries.	Holm and Sander (1994)

Modified from Pearl, F.M.G., Sillitoe, I., Orengo, C.A., 2015. Protein Structure Classification. eLS, pp. 1–10.

Sequence-based methods for recognising domains in proteins

In CATH, all new query structures from the PDB are also scanned against sequence profiles or hidden Markov models (HMMs) built with SAM (Sequence Alignment and Modelling) (Karplus *et al.*, 1998) from representative domain structures in CATH. The best-matching HMM to the query is that with the lowest E-value, which is significant if it is less than 0.001.

BLAST (Altschul *et al.*, 1990) and HHsearch (Söding, 2005) are used in the ECOD pipeline to search PDB chain queries against existing domain data in the ECOD database. The protein chain is first searched with BLAST against a library of full-length chains from ECOD that have had domains identified. The domains in the most significantly-matching chain (i.e., a match with a sequence similarity E-value $< 2 \times 10^{-03}$) are used to infer domain boundary positions onto the query chain. Next, the protein chain is search with BLAST against a library of ECOD domain sequences. Domains are assigned individually to the best match (i.e., sequence similarity E-value $< 2 \times 10^{-03}$ and hit coverage $> 80\%$). Finally, to detect more remotely related domains, HHblits (Söding, 2005) is used to generate a sequence profile of the query, which is then searched against the ECOD representative domain profiles using HHsearch (Cheng *et al.*, 2014).

Ab-initio methods for recognising domains in proteins

When there are no existing fold and domain matches to assist in defining domain boundaries, it is often useful to apply *ab initio* methods. Three *ab-initio* methods are used in CATH to identify protein domains: DETECTIVE (Swindells, 1995), DOMAK (Siddiqui and Barton, 1995), and PUU (Holm and Sander, 1994). Each algorithm uses a different method to identify domain boundaries, but they all use information on contacts between residues in the structure. They are all able to predict boundaries for both contiguous and discontinuous domains. DETECTIVE searches for the hydrophobic core of each domain. DOMAK randomly divides up a protein to maximise intra-domain contacts and minimise inter-domain contacts. PUU analyses the motion of predicted domains in relation to each other.

The majority of the chains that come into CATH are automatically chopped into domains using the ChopClose, CATHEDRAL and HMM protocols. However, due to the strict criteria imposed for quality control purposes, around 5% of chains need manual curation which is guided by the *ab-initio* methods.

Table 2 summarises the structure, sequence and *ab-initio* methods used to assign domain boundaries for domains classified in CATH.

Hierarchical Structural Classification

The three major domain structure classifications: SCOP, CATH and ECOD, use similar hierarchical classifications, with a few differences between them (Fig. 3). In the CATH classification the main levels from top to bottom are: class, architecture, topology or fold, homologous superfamily, and family. In the SCOP classification the different levels are: class, topology or fold, superfamily, and family. In the ECOD classification, which specialises in detecting remote homologies, there are five main levels: architecture, possible homology, homology, topology or fold, and family. These different levels will be discussed below.

Class

The protein class (C-level) considers the proportion of residues within a structure that fall within α -helix and/or β -strand secondary structure elements. There are three major classes: mainly α , mainly β , and a mixture of α and β . SCOP separates the latter into $\alpha + \beta$

Fig. 3 Comparison of the structural classification hierarchies used by SCOP, CATH and ECOD. The single letter used to represent a particular level has been included. While there are many similarities between the resources, there are clear differences such as the addition of the possible homology (X) level in ECOD, the lack of an architecture level in SCOP, and no class level in ECOD.

and α/β , giving this resource four main classes. CATH considers these as one class after finding considerable overlap between them since their original description in [Levitt and Chothia \(1976\)](#). CATH has a fourth class that represents domains with few secondary structures. Class is not featured in ECOD.

Architecture

Protein architecture (the A-level) describes the 3D spatial arrangement of secondary structure elements, independent of any connectivity information. Currently in CATH there are 41 different architectures: 5 mainly α , 21 mainly β , 14 α and β , and 1 in few secondary structures. Each architecture can represent 3D arrangements of secondary structures with diverse connectivities, which is represented by the topology level. There are more β -based architectures as constraints on the packing of β -sheets lead to very distinct and easily recognisable architectures such as β -barrels, β -prisms, and β -propellers.

Topology or fold similarity

The topology of a protein domain is given by its 3D spatial arrangement together with connectivity information, i.e., two domains having the same fold should have the same sequence of secondary structure elements packed together in similar orientations in 3D. In CATH, protein domains that have significant structural similarity to each other (i.e., a SSAP score of ≥ 70), but no sequence or functional similarity, are grouped into the same T-level. ECOD sub-classifies its A-levels into possible homology (X-levels), to represent groups of domains that have incomplete evidence for being homologous ([Cheng et al., 2014](#)). The T-level in ECOD comes after the homologous superfamily, H-level, rather than the A-level, so homologous domains are subdivided into topology-based groups. This is because in some superfamilies, relatives can diverge structurally to such an extent that they could be considered to have different folds. In CATH this structural variation is captured by grouping homologues into different structurally-similar clusters (SC5s), where relatives superpose within 5 Å RMSD or less.

Homologous superfamily

Domains are grouped at the homologous superfamily level (H-level) where there is clear evidence of homology, i.e., the domains have evolved from a common ancestor. There can be considerable divergence across some superfamilies in terms of structure,

sequence and function. Fig. 4 shows that for representative relatives (i.e., representatives of relatives clustered at 95% sequence identity) within the same superfamily there can be a wide range of sequence identity scores.

For these very remote homologues, structure and function information can be used to detect an evolutionary relationship. Protein structure is generally much more conserved than sequence, making it easier to use in homology detection. As with sequence, there can also be considerable variation of structure across some superfamilies (Fig. 5).

Fig. 4 The distribution of sequence identity scores between pairs of representative homologous domains (non-redundant at 95% sequence identity) in CATH. All-against-all comparisons were performed using BLASTp with the default maximum E-value (i.e., 10) and default maximum number of target sequences (i.e., 500). If we relax both of these thresholds then we can see results from comparing more relatives which have even lower sequence identities, however there are too many false positives (data not shown).

Fig. 5 The distribution of structural similarity scores (using SSAP) between pairs of homologous domains in CATH.

Homologous family

Protein families consist of close relatives which generally have at least 30% pairwise sequence identity to each other, or evidence of close functional similarity, or taxonomic similarity. SCOP places domains in the same family if they have at least 30% sequence identity, or if they have some level of sequence identity and a similar function (Hubbard *et al.*, 1997). These families generally consist of taxonomically close relatives. CATH recognises functionally-related families of homologues through similarities in specificity-determining residues (see FunFHMmer in Section “Capturing Functional Diversity by Sub-Classification of Super-families”). ECOD domains are scanned against Pfam family HMMs to define family memberships and those domains that cannot be assigned to a Pfam family are grouped together by HHsearch (Cheng *et al.*, 2014).

Nearest-Neighbour Clustering

Nearest-neighbour clustering is an alternative to hierarchical classification. A structural comparison program such as Dali or VAST+ is used to compare one or more structures against each other or the whole PDB archive, for example. These resources provide lists of the closest structural neighbours, where the significance of the matches is determined by taking the distribution of scores and calculating a Z-score for each match. In Dali (Holm and Sander, 1995; Holm and Laakso, 2016), the structures from the Z-score-ranked list can then be clustered to visualise the structural relationships as a dendrogram. These resources simply provide information on structural similarity and do not take into account any other information (e.g., similarity in functional features or rare sequence motifs). Hence they do not distinguish homologous and analogous relationships.

The resources providing nearest-neighbour clustering and hierarchical classification are listed in Table 1.

Integration of the SCOP and CATH Resources

While SCOP and CATH are both hierarchical classifications, there are differences in their methodologies. For example, while both resources use both manual and automated methods to identify domains and assign them to superfamilies, SCOP relies more on manual curation. There are also differences in the philosophies behind what defines a structural domain: SCOP recognises domains when they are found to occur across different multi-domain contexts, whereas CATH also uses physical information such as the domain size, globularity, and compactness (Hadley and Jones, 1999).

The Genome3D collaborative project (Lewis *et al.*, 2013, 2015) was developed to integrate the important information in these two resources and use it to annotate genomic sequence data. Well-known structure prediction resources from six structural bioinformatics groups across the UK were incorporated: DomSerf (Buchan *et al.*, 2010), FUGUE (Shi *et al.*, 2001), Gene3D (Yeats *et al.*, 2011), pDomTHREADER (Lobley *et al.*, 2009), Phyre2 (Kelley and Sternberg, 2009), SUPERFAMILY (Gough and Chothia, 2002), and VIVACE. UniProt sequence data from ten genomes were annotated by these resources, which used SCOP- and CATH-based structural data to predict structural domains within the sequences and build structural models.

Consensus superfamilies were identified between SCOP and CATH to also facilitate mapping between the structure predictions. This was done by comparing pairs of SCOP and CATH domains, and calculating the residue overlap between them. SCOP and CATH superfamilies sharing a high proportion of significantly overlapping domains were considered equivalent. The level of equivalence was graded into Bronze, Silver and Gold Standard categories, with gold being the best. A pair of superfamilies (SCOP-CATH) meeting the Bronze Standard are “more similar to each other than to any other superfamily” (Lewis *et al.*, 2013). A Silver Standard pair meets the Bronze Standard and, in addition, at least 80% of domains from each superfamily map between them with an average residue overlap of at least 80%. A Gold Standard pair, in addition to the other two Standards, has domains that map between both superfamilies with a minimum of 80% residue overlap. Mapping SCOP v1.75 to CATH v4.0 domains: 938 Gold Standard, 213 Silver Standard and 388 Bronze Standard superfamily consensus pairs were found. The Gold Standard superfamily pairs are currently being integrated into the InterPro resource (Finn *et al.*, 2017), where they have been added in as homologous superfamily entries. This work has greatly increased the coverage of both Gene3D and SUPERFAMILY domain and superfamily entries in InterPro.

Current Status of the Protein Structural Universe

As previously mentioned, as of November 2017, there are almost 135,000 entries in the PDB. Table 3 describes the statistics for SCOP, CATH and ECOD. The SCOP resource was last updated in 2009, which accounts for the large difference in the number of PDBs processed and domains identified between the three resources.

Of the 110,800 domains in SCOP v1.75, 15% of domains are mainly α -helical in structure, 24% are mainly β -structure, and 49% have mixed α/β or $\alpha + \beta$ structural content. The CATH classification has processed 90% of PDBs, and contains almost 445,000 structural domains. Currently, 22% of the domains in CATH superfamilies are mainly α -helical in structure, 25% are mainly β structure, and over half (52%) have mixed $\alpha\beta$ secondary structure content. The ECOD classification has processed slightly more PDBs than CATH (~3500) and has detected more remote homologies, leading to a smaller number of superfamilies. It is expected that the domains in ECOD follow a similar distribution, but as the ECOD hierarchy starts at the architecture level rather than class, it was not possible to separate the domains by class information.

All three of these resources provide free, publically available data. CATH and ECOD provide frequent updates, with ECOD publishing an update each week and CATH publishing an update every day. In addition to offering the daily-updated CATH

Table 3 Statistics for the SCOP, CATH and ECOD resources

	<i>SCOP v1.75</i>	<i>CATH v4.2</i>	<i>ECOD v199</i>
PDBs processed	38,221	131,091	134,556
Domains identified	110,800	434,857	577,454
Number of folds	1195	1391	3738 ^a
Number of superfamilies	1962	6119	3537
Number of families	3902	68,069	13,426

^aAll SCOP and ECOD data were obtained from their websites, apart from the number of folds, which was calculated by finding the number of unique X.H.T strings in their download file.

structural domain and superfamily assignment data, there are also CATH-Plus releases with a wealth of extra data. The latest CATH-Plus (version 4.2) release was recently published in October 2017. This release comprises 434,857 protein structural domains, grouped into 6119 homologous superfamilies. Other data included in CATH-Plus includes: functional family data, function annotations from Gene Ontology (GO) and Enzyme Commission (EC) data; enzyme function evolution information with FunTree; species diversity information from taxonomic information, structural diversity information through structurally similar groups (SSGs) and superposition images; domain organisation information with ArchSchema (see Fig. 6). Additional sequence domain data is also provided by Gene3D (see Section “Structural Families in the Genomic Era”), which contributes ~95 million sequence domains to CATH. Briefly, Gene3D uses the curated structural information in CATH to predict domain boundaries for UniProt sequences, which do not have a known 3D structure.

There is an uneven distribution of domains across the protein fold universe. For example, of the 1391 folds in CATH, the top five most populated folds account for 30% for all structural domain sequences in CATH. The top five most populated folds, including the: Rossmann fold, TIM barrel, and Immunoglobulin fold, are shown in Fig. 7. This distribution bias is also clearly seen in the homologous superfamilies as the most populated 100 CATH superfamilies represent almost half (49%) of all domain sequences.

Structural Families in the Genomic Era

Structural databases have increased massively over recent years. However, the sequence databases continue to grow even faster, with ~100 million sequences now in UniProt-KB. These numbers will continue to grow rapidly over the coming years. New sequence read technologies that provide longer reads will make sequencing animal genomes more easy and affordable, and will contribute to an explosion in genome sequences over the coming years. Despite this, the various resources for predicting domain families from sequences (see Table 4) have continued to cope with the current increase in datasets (Lewis *et al.*, 2017; Finn *et al.*, 2017).

Many of the family annotation resources such as Pfam and Gene3D use sequence profiles in the form of HMMs, built from structural representatives of a family, to recognise relatives in genome sequences. The sensitivity of HMMs comes from their ability to capture information of conserved residue positions across a given family, and positions where residue insertions and deletions are more tolerated.

One reason for this ability to scale arises from improvements in HMM-based software with large speedups produced recently by the HMMER package (Eddy, 2011). The Gene3D v16 resource assigns domains for over 52 million protein sequences, producing over 95 million domain assignments (Lewis *et al.*, 2017). For each CATH S95 sequence, a HMM is built using 1–2 rounds of Jackhmmer (for details see Lewis *et al.*, 2017). These HMMs are then scanned against the protein sequences using the hmmsearch program as part of the HMMER package. Sometimes different HMM models overlap the same region and it is necessary to resolve a final set of non-overlapping domain annotations. Gene3D makes use of the cath-resolve-hits (CRH) software (available from the cath-tools resource pages (see Relevant Websites Section)), which uses dynamic programming to efficiently select the optimal set of non-overlapping domains, using the bit score of each hit as a measure of the hits overall quality. Importantly CRH is both extremely fast, memory efficient and can deal with discontinuous domain assignments whilst still finding an optimal solution.

Evolution of Protein Structure, Sequence and Function

Evolution of Protein Folds

As more and more structural data and functional annotations accumulated in protein structure databases, such as CATH and SCOP, it appeared likely that only a limited number of folding arrangements exist in nature. For example, there now are 131,091 protein structures in the CATH database (version 4.2) that have been classified into 434,857 structural domains, which is a nearly 50% increase in the number of domain structures over the last five years. However, the number of folds identified has increased very slowly with still only 1391 different folds identified (Dawson *et al.*, 2017).

Protein fold similarity can often provide important clues regarding the functional role of a protein. However, studies on different folds have shown that protein domains that share the same fold can show functional divergence (Martin *et al.*, 1998). As mentioned already above, some folds, also known as ‘superfolds’, are highly populated and occur more frequently than others.

Fig. 6 Example of a superfamily summary web page, which is available for each superfamily in CATH. These pages contain information on: function annotation (GO and EC terms), species diversity, structural diversity, sequence diversity, and functional families.

These generally adopt Rossmann and TIM barrel folds or other folds which possess very regular architectures such as layers of beta-sheets and/or alpha-helices (Orengo *et al.*, 1994). It has been suggested that the regularity of these folding arrangements may provide a stable core to support diverse sequences. Hence, it is not surprising that they comprise multiple superfamilies. For example, the Rossmann fold comprises 130 superfamilies and the TIM barrel constitutes 30 superfamilies in the CATH database.

Exploiting CATH Superfamilies to Examine the Evolution of Protein Functions

The CATH-Gene3D resource (Dawson *et al.*, 2017; Lewis *et al.*, 2017), which brings together evolutionarily-related structural and sequence domains into superfamilies along with their functional annotations, provides an ideal platform to systematically analyse and explore how function is modulated by sequence and structural changes.

Fig. 7 Fold counts based on the number of CATH structural domain sequences. The top five folds account for 30% of all structural domain sequences in CATH. A structural representative from each of the top five folds is illustrated, coloured according to their secondary structure content.

Table 4 Example resources with genome annotations of structural assignments along with details of some of their unique features

Resource	Description	Useful Features
PFAM http://pfam.xfam.org/	Comprehensive prediction of protein families using HMMs.	User friendly tools to scan datasets. Extensive annotations of the Pfam families that helps to functionally interpret results. Combines families into larger Clans based on shared evolutionary origin.
InterPro https://www.ebi.ac.uk/interpro/	Integrates multiple resources assigning protein families domains and functional sites.	Scope and annotations has proven it to be a cornerstone of function prediction. Annotates entries with extensive text, GO terms etc.
Gene3D http://gene3d.biochem.ucl.ac.uk/	Predicts CATH structural domains.	Powered by CATH and so is largely up to date relative to the PDB. Functional Family level provides state of the art function and structure prediction.
SUPERFAMILY http://supfam.org/SUPERFAMILY	Predicts SCOP structural domains.	Established resource that is widely used in research projects e.g., provides tools for comparative genomics and genome annotations.
Genome3D http://genome3d.eu/	Provides consensus structural annotations and 3D models for model organisms.	Integrates SCOP, CATH, SUPERFAMILY, Gene3D, FUGUE, THREADER, PHYRE.

Modified from Pearl, F.M.G., Sillitoe, I., Orengo, C.A., 2015. Protein Structure Classification. eLS, pp. 1–10.

Fig. 8 Structural diversity in the “Nitrogenase molybdenum iron protein domain” superfamily (CATH ID: 3.40.50.1980). This superfamily is highly structurally diverse with nine structurally similar clusters. The figure shows structures of: (A) the smallest, (B) largest domain and (C) superposition of representative non-redundant superfamily members to highlight the conserved structural core.

Some CATH superfamilies are very highly populated and universal to all kingdoms of life (Reid *et al.*, 2010). As previously mentioned, the 100 most highly populated superfamilies in CATH account for half of all known protein domains. The domain relatives in these superfamilies can incorporate large amounts of structural and functional diversities even though they share a conserved structural core. In some superfamilies relatives can vary in size by as much as 5-fold (Fig. 8(A) and (B)). This has been described as the ‘Russian doll’ effect (Swindells *et al.*, 1998). However, most relatives across a superfamily share the same common structural core comprising at least 50% of their structure (Fig. 8(C)).

Mechanisms of functional divergence

Various studies (Das *et al.*, 2015; Todd *et al.*, 2001; Reeves *et al.*, 2006; Brown and Babbitt, 2014; Galperin and Koonin, 2012) on the evolution of function in diverse superfamilies have illustrated that proteins can evolve new functions by one or a combination of different molecular mechanisms (Fig. 9). Some of these mechanisms include use of different sets of residues in binding or active site, addition of secondary structure embellishments to the core protein structure which alters the geometry of the active site or an interface on the protein or due to domain-shuffling in multi-domain proteins which can alter the context of the domain. Examples of some these mechanisms of functional divergence have been briefly discussed below.

Molecular tinkering

Relatively small changes in a binding or active site can result in changes in shape, physicochemical or other characteristics of the site which can alter the function of a protein significantly. Although, the active site may be highly conserved in some diverse enzyme superfamilies, for example, functionally diverse enzymes of the α/β hydrolase superfamily utilize the same catalytic triad (Todd *et al.*, 2001), a recent study indicated that relatives of a large number of diverse enzyme superfamilies show changes in catalytic machinery (Furnham *et al.*, 2016). One such superfamily is the Aldolase Class I superfamily, the members of which can carry out reactions with 31 different enzyme chemistry by using different sets of catalytic residues.

Structural mechanisms

Superfamily relatives can also vary in size to a great extent. For more than 150 CATH superfamilies, at least a 2-fold variation in the size has been observed between the most diverse domains and up to 5-fold in some superfamilies (Reeves *et al.*, 2006). The structural diversity among the domains can range from small changes within the active site to extensive embellishments which can alter their function, as seen in the HUP (High-signature proteins, UspA, and PP-ATPase) superfamily (Dessailly *et al.*, 2013).

Multi-domain context

Changes in the multi-domain architecture (MDA) of a protein can significantly alter its context, thereby modifying its function. For example, enzymes of the Thiamine pyrophosphate (TPP)-dependent superfamily, catalyse a large number of different reactions using TPP as the co-factor, by changing the domain partnership which alters the size and physicochemical properties of the active site pocket (Vogel and Pleiss, 2014).

Fig. 9 Functional divergence in protein domains can arise due to one or combination of some of the following molecular mechanisms: (A) changes in active site residue, (B) gene fusion, (C) structural embellishments around active site and (D) structural embellishments changing interfaces. Modified from Das, S., Dawson, N.L., Orengo, C.A., 2015. Diversity in protein domain superfamilies. *Current Opinion in Genetics and Development* 35, 40–49.

In the majority of the large functionally diverse superfamilies, functional diversity generally results from a combination of different molecular mechanisms.

Capturing Functional Diversity by Sub-Classification of Superfamilies

One way to capture and understand this functional diversity among protein homologues is to further classify the superfamilies into functional groups. This functional classification also helps in inheriting annotations between homologous proteins that are most likely to perform the same function. Additionally, it allows identification of residues that are highly conserved among family members and which are most likely to have a functional role.

The CATH superfamilies have been functionally classified into Functional Families (FunFams) that group together relatives likely to have highly similar functions. The functional classification is derived from sequence similarities of superfamily relatives by optimal partitioning of a hierarchical sequence clustering tree for the superfamily which is generated by an agglomerative clustering algorithm (Lee *et al.*, 2010). This optimal partition is done by the FunFHMmer algorithm (Das *et al.*, 2016) which is based on maximising coherence of conserved residues within clusters and separation of differentially conserved residue positions (also known as functional determinants or FDs) between different clusters. The resulting clusters from the partition make up the FunFams for the superfamily. The FunFams have been shown to be functionally coherent based on different benchmarks using known functional annotations from the EC, GO, and annotations from the gold-standard SFLD superfamilies (Das *et al.*, 2016).

Hidden Markov Models (HMMs) are generated for all FunFams in CATH superfamilies and are used for predicting functions for uncharacterized sequences. When an uncharacterised query sequence is scanned against the library of CATH FunFam HMMs, it provides FunFam assignments. This provides both structural and functional insights for identified sequence domains. Functions for the query sequence domains are predicted by inheriting the known functional annotations of the sequence relatives of the assigned FunFam. This function prediction pipeline has been consistently ranked among the top 10 performing methods by the Critical Assessment of Function Annotation (CAFA) challenges (Radivojac *et al.*, 2013; Jiang *et al.*, 2016), an independent large-scale assessment of function prediction methods using different benchmarks and evaluation metrics. A web server (See Relevant Websites Section), Fig. 10(A) has been set up to allow users to submit query sequences in FASTA format for assignment to CATH FunFams where possible for the constituent domains of the query sequence (Das *et al.*, 2015). For each of the constituent FunFams of the query sequence, the server (Fig. 10(B)) reports functional annotations of the FunFam domain relatives and highly conserved residues for alignments with sufficient information content.

Fig. 10 CATH sequence search: (A) The server (http://www.cathdb.info/search/by_sequence) takes a query protein sequence (in FASTA format) as input and scans it against the library of CATH-FunFam HMMs. (B) The CATH FunFam matches for the constituent domains of the query sequence are reported along with their corresponding E-values.

The functional classification also provides a platform to detect subtle changes in conservation patterns that can suggest shifts in binding specificities or catalytic machineries of domain relatives in a superfamily. This kind of information would be helpful to guide experiments for target selection which would help to characterise unusual domain relatives of all protein superfamilies.

Conclusions

Protein structural classifications categorise protein structures deposited in the PDB according to their 3D structural characteristics and evolutionary relationships. There are three major classifications publically available to use: SCOP, CATH, and ECOD. A range of algorithms have been developed to recognise domain boundaries within protein structures using sequence-, structure-, and ab-initio-based methods. Algorithms have also been developed to detect homologous relationships, which are used to assign these domains into homologous superfamily groups and thereby classifying them within a classification hierarchy.

Nearest-neighbour clustering methods are an alternative way of searching for structural homologues. Structural comparison methods (e.g., Dali and VAST +) are used to compare one or more query structures against each other or the whole PDB archive,

for example. Only information on structural similarity is provided, offering a fast way to generate lists of potential structural relatives and analogues.

SCOP, CATH and ECOD have many similarities in their protein structural classification hierarchies, which are discussed in Section “Hierarchical Structural Classification”. Consensus SCOP and CATH superfamily data have been identified through the Genome3D project and are currently being integrated into the InterPro resource to increase the coverage of data for the SUPERFAMILY and Gene3D resources (see Section “Integration of the SCOP and CATH Resources”).

A look into the current status of the protein structural universe highlights the large amounts of structural data that has been analysed and made publically available. As seen over recent years, there is an uneven distribution of domains assigned to protein folds and superfamilies. For example, the 100 most-populated CATH superfamilies have consistently accounted for around half of all structural domain sequences.

Taking a look at the vast amounts of genomic sequence data available, Section “Structural Families in the Genomic Era” describes how structural family data is used to annotate these data, which do not have any known structures. HMM libraries are built from structural domain data in CATH, which are then used by the sister resource Gene3D to scan genome sequences against to find significant structural matches for domain and homology detection. These scanning methods and libraries provide a very powerful way to annotate genomic data.

CATH superfamilies and functional families can be used to examine the evolution of protein sequence, structure and function. The mechanisms behind these divergences are discussed in Section “Evolution of Protein Structure, Sequence and Function”. Superfamily superpositions illustrate any structural diversity within a superfamily, yet clearly show that even diverse superfamily have a highly conserved structural core. Functional family data are an important part in exploring functional diversity within a superfamily, determining functional relatives and in annotating protein function for unknown sequences.

Secondary Structure Prediction

Introduction

The study of proteins is fuelled by the desire to understand their function. The molecular understanding of function requires the understanding of structure. However, determining the three-dimensional (3D) structure of proteins is a highly non-trivial process. Despite substantial advances in technologies, the experimental determination of a single protein is still costly and might take years. Conversely, the advent of next generation sequencing techniques has tremendously increased the amount of raw sequence data about which there is very little structural knowledge (Goodwin *et al.*, 2016; Martinez and Nelson, 2010). Due to ever decreasing costs, the speed at which this sequencing data is being generated far outpaces the annotation of the data with structural (or functional) knowledge. This creates a divide that has been referred to as the sequence-structure gap. For instance, the UniProtKB database currently contains almost 60 million proteins which are at most 90% identical (The Uniprot Consortium, 2016; Suzek *et al.*, 2015). In contrast, the Protein Data Bank (PDB), the major database of protein 3D structures, contains just 48,000 protein structures at that similarity cutoff (Berman *et al.*, 2000).

The prediction of the protein secondary structure is one step toward bridging this gap. Due to its simplicity and elementary importance, secondary structure is also one of the earliest features that has been predicted from sequence and has grown over many decades into a mature field where predictions can be performed at relatively little computational cost, yet at a high performance.

If the 3D structure could be predicted directly, then one would also have an implicit prediction of secondary structure. However, despite crucial breakthroughs in the last 5–10 years, the number of proteins for which 3D structure can be predicted from sequence remains limited (Kinch *et al.*, 2016; Hopf *et al.*, 2012; Moult *et al.*, 2016; Marks *et al.*, 2012). Even for most proteins for which comparative modelling can infer 3D structures (Biasini *et al.*, 2014; Yang *et al.*, 2011), dedicated secondary structure prediction methods still tend to perform better (Eyrich *et al.*, 2001). Additionally, the computational costs of more advanced methods are substantial which is in contrast to the decrease in resources needed for generating novel sequence (Muir *et al.*, 2016). Hence, both effective and efficient annotation of this sequencing data is necessary.

On top of the knowledge about the structural elements, secondary structure predictions also serve as input to predict more complex protein features such as disordered regions, interaction sites or aspects of protein function. Solvent accessibility is another feature of protein structure and often predicted by many of the tools for secondary structure prediction.

This contribution succinctly summarizes the underlying biological concepts of protein secondary structure and continues discussing some of the main concepts in the field of secondary structure prediction before presenting a selection of such methods in more detail. Finally, the level at which state-of-the-art methods perform is examined.

Background

Secondary Structure Elements in Protein Folding

Protein 3D structure is encoded by its amino acid sequence which is sometimes misleadingly referred to as the “primary structure”. The order in which the 20 biogenic amino acids are arranged uniquely defines the structure and determines its folding in 3D (Anfinsen, 1973). Amino acids are linked by a covalent, so-called peptide bond which forms the backbone of the protein. Given the chemical properties of the amino acids and the physical constraints of this bond, the number of possible protein conformations is immense. The forces that drive the folding process that strives for a stable energetic minimum, are non-covalent interactions such as electrostatic interactions, much weaker but more common van der Waals interactions, or the hydrophobic effect, i.e., non-polar components aggregating in water (Kessel and Ben-Tal, 2011).

For the formation of secondary structure elements, a specific type of electrostatic interactions, the hydrogen bonds, are often claimed as the main stabilizing force. While this is most likely not the case, they still give structure to the elements in question and are important to overall protein stability (Kessel and Ben-Tal, 2011). Hydrogen bonds form between two dipoles which act as donor and acceptor, such as two atoms of amino acid side chains. However, in the case of secondary structure elements, the relevant atoms are part of the peptide bonds. Here, a hydrogen atom that is covalently bound to a nitrogen, gets in proximity of, and is therefore attracted by, an electronegative oxygen (Fig. 1). The stable secondary structure elements then further develop interactions between themselves and form a tertiary structure.

Various types of secondary structure are observed repeatedly out of which helices and strands are the most prominent ones. Both are characterized by specific patterns of hydrogen bonds. Due to these patterns, those two types are also often referred to as “regular secondary structure”. Most prediction methods target three “states” using those two regular types and merging everything else into the state “other”.

Fig. 1 α -helical and β -sheet secondary structure elements. The two most common secondary structure elements are visualized in PyMol (Schrodinger, 2015). Above, the protein is visualized in a cartoon view that highlights the secondary structure elements and hides details such as the amino acid side chains. Below, the protein backbone, without amino acid sidechains, of parts of the same secondary structures are shown in a sticks view. Here, oxygen atoms are colored blue, nitrogen yellow, hydrogen red and all others grey. Hydrogen bonds between atoms of the protein backbone are visualized as yellow dashed lines. (a) The human protein myoglobin is shown with α -helices highlighted in red and the rest of the protein in green (PDB identifier 3rgk). This is an “all-alpha” protein fold which consists of only α -helices and loops. (b) A part of the human vascular cell adhesion molecule is shown with β -sheets highlighted in yellow and loops in green. A small, single-turn α -helix can be seen in red at the left side.

Helices (α , 3_{10} , π)

As mentioned above, helices are defined by a repeating pattern of hydrogen bonds between residues. In an ideal α -helix, these bonds form between residues i and $i + 4$. This type of helix allows a relatively compact formation where four residues form a single “turn” of a helix. 3_{10} helices are more compact with just three residues (or ten atoms) forming a single “turn”. π -helices on the other hand are wider and complete one “turn” every five residues. Among these three types, α -helices are energetically most favorable and thus most often observed. In literature and the output of prediction methods, helices are typically abbreviated by the letter H.

Strands and sheets (β -strands, parallel and antiparallel β -sheets)

β -sheets are a more spacious type of secondary structure formed from β -strands. Strands consist of the protein backbone “zig-zagging”, typically for four to ten residues. Single β -strands are not energetically favorable. However, they can form β -sheets which are characterized by a pattern of hydrogen bonds between the residues on two different β -strands. Residue i in strand 1 forms a hydrogen bond with residue j in strand 2. The next bond can be formed in two different ways: either residue $i + 2$ in strand 1 binds to $j + 2$ in strand 2 (referred to as a parallel β -sheet), or residue $i + 2$ in strand 1 binds to $j - 2$ in strand 2 (referred to as antiparallel β -sheet). In contrast to the situation for helices, the hydrogen bonding residues in β -sheets might be far away in sequence. Most β -sheets are formed from more than two strands. Typically, β -strands and -sheets are abbreviated by the letter E.

Other/loops

All residues that do not participate in helices or strands are often joined in one category as “other”. Historically, this is also referred to as “loop” or, very misleadingly, as “(random) coil”. Although the residues in question do not form hydrogen-bonded regular secondary structure, they are often constrained by bonds to other residues and are certainly not all random. Some methods distinguish different types within the class “other” such as “(reverse) turns” or “bends” where the residues in question change the direction of the amino acid chain. This non-regular class is typically abbreviated by the letter L.

Inference of Secondary Structure Elements From 3D Protein Structures

DSSP

Define Secondary Structure of Proteins (DSSP) is the standard tool for the annotation of secondary structure elements from protein structures (Kabsch and Sander, 1983; Touw *et al.*, 2015). Based primarily on hydrogen bonding patterns and some geometric constraints, it assigns every residue to one of eight possible states. States corresponding to helical structures are α -, 3_{10} - and π -helices. β -bridges are short fragments that show β -sheet like binding patterns. Multiple consecutive β -bridges form the state referred to as β -ladder. Multiple ladders can then form the above-mentioned β -sheets. However, DSSP does not have a separate state for β -sheet residues and the one for β -ladders is used. The remaining three states, called turn, bend and other, describe loop structures. Typically, secondary structure prediction methods simplify these eight states into just three: α -helix, β -sheet and loop.

STRIDE

Given a high-resolution 3D structure, annotation of secondary structure elements remains a matter of definition to some degree. STRIDE represents an alternative approach to DSSP. It aims to provide secondary structure assignments that are more consistent with the assignments performed by experimentalists who determined the protein structure (Frishman and Argos, 1995; Heinig and Frishman, 2004). Next to hydrogen bonds it includes other aspects such as the backbone geometry in the form of dihedral angle propensities. Another difference to DSSP is that some of its decision thresholds have been optimized on data from the PDB which makes it a knowledge-based approach. Nonetheless, the agreement between DSSP and STRIDE annotations is very high at 95% (Martin *et al.*, 2005).

Assessing Secondary Structure Predictions

Assessing secondary structure predictions requires all the care generally exercised when evaluating the performance of machine learning models. One aspect is the careful choice of a meaningful scoring model.

The simplest and most commonly used performance measure is the three-state per-residue accuracy referred to as Q_3 . It represents the fraction of all residues that have been predicted accurately in the three states helix, strand, other. Despite its popularity, this score has several shortcomings. Q_3 ignores the uneven distribution in the three states: most residues are in the state other, i.e., methods that poorly predict the more important regular states (in particular the least common state of strand) might still reach high performance. Additional scores to measure these aspects include Q_H and Q_E , the percentages of correctly predicted helix and strand residues. Many other scores have been proposed and are useful in different contexts (Rost and Sander, 1993b). All these per-residue ignore the fact that secondary structure segments span over several residues. This shortcoming is corrected by per-segment scores (Rost *et al.*, 1994). The simplest such score compares the average length of predicted and observed segments. More advanced is a composite score referred to as segment overlap (SOV) (Fidelis *et al.*, 1999). Instead of measuring single-residue accuracy, SOV scores the correct placement of secondary structure segments. Such scores tend to give leeway with respect to predicting the precise begin and end positions of segments. Predictions that roughly predict the location of most segments score high.

Given performance measures, one also needs a test dataset to evaluate predictions. Authors exercise varying degrees of care in trying to report unbiased performance estimates. Best would be to assess all relevant methods based on proteins that differ substantially in sequence from those used for development of any of the methods.

One effort for such an assessment was EVA, a server that collected newly released protein structures as an unknown test set and then automatically queried secondary structure prediction methods for their predictions of those proteins' secondary structure elements (Eyrich *et al.*, 2001). This process was performed on a weekly basis and the results published online. A similar concept was followed by LiveBench (Rychlewski and Fischer, 2005). Unfortunately, both servers have now been offline for more than 10 years. CAMEO is a current effort in automated protein structure prediction evaluation and its operators have stated that it may include an assessment of secondary structure prediction in the future if there is a community interest (Haas *et al.*, 2013).

Approaches

Amino Acid Propensities

Since the very beginning, the prediction of secondary structure elements was based on the fact that amino acid occurrences are not evenly distributed between those elements but show preferences (Kessel and Ben-Tal, 2011). For example, due to their compactness helices often contain amino acids with small, or more precisely linear, side chains such as alanine, glutamic acid or methionine. On the other hand, proline is rarely found in helices. Its pyrrolidine ring and bound backbone amide group disturb the geometry and hydrogen bonding pattern of the helix. This leads to a kink in the helix that is energetically unfavorable and gives proline the nickname "helix breaker". In the same way β -sheets have preferences for certain amino acids, in particular at their termini. Although weak, these propensities suffice to predict secondary structure better than random. In one way or another even the most recent methods developed today still exploit such features. However, finding the right relationships is far from trivial as the formation of secondary structure depends on more than just the local amino acid content. The most extreme evidence for this are so-called chameleon sequences. These sequence fragments can fold into both helix and strand conformations depending on context (Jacoboni *et al.*, 2000; Guo *et al.*, 2007; Li *et al.*, 2015).

Basic Concepts of Secondary Structure Prediction

Even before high-resolution protein structures became available, the earliest methods used exactly these amino acid propensities mentioned in the previous section together with empirically defined rules to gain insights into the secondary structure content of proteins of interest. For example, Szent-Györgyi and Cohen described the relationship between helices and proline as outlined above (Szent-Györgyi and Cohen, 1957). Chou and Fasman determined a simple rule as to which a clustering of certain helix or strand “former” residues leads to formation of the respective secondary structure element (Chou and Fasman, 1974). One could refer to those early approaches as “first generation” methods because they ultimately scanned for features of single residues.

Stepping up, the “second generation” methods improved performance by including more information. The basic idea was to consider the sequence neighborhood of a residue, i.e., for a residue at position i those before it ($i - 1$, $i - 2$, ...) and those directly after it ($i + 1$, $i + 2$, ...). At the end of the 80s such statistical approaches were complemented by the first machine learning solutions. While any of the usual machine learning models is potentially applicable, (artificial) neural networks (NNs) have been particularly popular in the field. Early machine learning-based methods used a limited set of input features which may be as simple as the amino acid sequence itself. Typically, the sequence would be parsed in a sliding window of uneven size X , i.e., to predict the secondary structure of the central amino acid residue, all $\lfloor X/2 \rfloor$ neighboring residues are considered. With increasingly complex models and more computational power becoming available, a multitude of other features was added to increase the chances of the model finding the intricate correlations between amino acids which lead to a respective secondary structure. This allowed to predict strands and helices at equal levels of accuracy (Rost and Sander, 1993b). However, all those tools seemingly hit a performance limit since the information available within the window was too small and increasing the window size introduced more noise than signal.

This led to the leap into the “third generation” methods that combined machine learning with evolutionary information (Rost and Sander, 1993a). To use evolutionary information, one first needs to create a multiple sequence alignment (MSA). Toward this end, one needs to find all proteins with sufficiently high sequence similarity to a query which guarantees that those proteins have similar secondary structure. Most important here is not the number of related proteins, but the amount of diversity, i.e., the sequences more distantly related are more important to improve the prediction than those that are very similar. The MSA is then converted into a position-specific scoring matrix (PSSM), often also referred to as “profile”. This profile can be used by the prediction method to replace a much simpler 20-dimensional binary vector with 1 for the amino acid at that position and 0 for all 19 amino acids not at that position. An example of a simple neural network with homology information as input is shown in Fig. 2.

Fig. 2 A simple feed-forward neural network using homology information for the prediction of secondary structure elements. On the left, the input sequence for which the secondary structure is to be predicted runs from top to bottom. Right of it, the position specific scoring matrix (PSSM) for this input sequence is shown. Such a PSSM is created for example by performing a PSI-BLAST query with the input sequence against a large sequence database. The matrix contains information about which amino acids are commonly found in homologous sequences and which substitutions are rare. Typically, these values are used as log-odds such that negative values determine an unlikely substitutions and positives ones a likely one. These values can then be used as input to the neural network which leads to 20 inputs for every residue. To allow for a better visualization, the network shown here uses a very small sliding window of just three residues. Therefore, when predicting the secondary structure state at position 6, the PSSM values of positions 5, 6 and 7 are used as input to the network. The three input nodes labelled -1 , 0 and 1 are in fact 20 nodes each, leading to a total of 60 inputs. These values are then fed through a hidden layer to the output layer which predicts one of the three secondary structure states. Weights on the connections between these layers are optimized during the training of the network. A typical neural network for the prediction of secondary elements may use a sliding window of size 13 and have hundreds of nodes in the hidden layer. In deep learning, more than one hidden layer is used and in recurrent neural networks nodes from one layer may be connected to those of a previous layer.

Over the last few years, increasingly cheap, yet powerful hardware capable of highly parallelized calculations has given a new rise to deep learning approaches that has also reached the field of secondary structure prediction. These approaches are also based on NNs. However, they have more than one hidden layer and their architecture often differs significantly from that of traditional feed-forward NNs.

Results and Discussions

Secondary Structure Prediction Methods

In the following, a few secondary structure prediction methods are described in more detail starting with some of the oldest approaches to the current state-of-the-art (Table 1). The methods were chosen to represent some of the historically most valuable publications, to give an overview of how the field developed and highlight some of the currently most promising methods.

Prediction based on amino acid composition statistics

GOR, named by the initials of its authors is an information theoretical approach first published in 1978 (Garnier *et al.*, 1978, 1996). Using a sliding window of 17 residues the method calculates the most likely secondary structure element based on amino acid propensities which were extracted from a database of proteins with known secondary structure. The method was later extended by updating the underlying database with more recent data in GOR II. In addition to the previous single-residue statistics, GOR III included correlations between pairs of residues, i.e., between the central amino acid and amino acids at all other positions in the window. GOR IV further increased the number of residue pairs considered. Instead of only pairs with the central residue, all possible residue pairs in the window were now included in the calculation. In 2002 the final version of the method, GOR V, further extended the approach by adding statistics of amino acid triplets, as well as by including homology information, choosing the windows size depending on sequence length and again updating the underlying database (Kloczkowski *et al.*, 2002).

Prediction based on two levels of neural networks

PHDsec is one of the earliest methods to apply machine learning to the task of secondary structure prediction and the first to harness homology information to further improve it (Rost and Sander, 1993a). The method is based on NNs and uses only sequence information as input. For a given input sequence an MSA with homologous sequences is constructed from the HSSP database (Sander and Schneider, 1991). Then the amino acid occurrences at every position in the sequence are calculated. The method uses a sliding window of 13 residues and every position translates to 21 input units which are fed with the amino acid occurrences from the MSA at that position. 21 units are required (as opposed to just 20) to model cases near the N- and C-terminus of the input sequence where parts of the sliding window are “empty”. The total 273 input units are connected to a hidden layer and an output layer which contains three nodes corresponding to an α -helix, β -sheet or loop prediction for the central residue in the sliding window. The output of this first NN is used as input to another NN with a 17-residue sliding window. This second layer aims to smooth the output such that segments are predicted more continuously. Later extensions to the method added more input features derived from the MSA as well as global amino acid composition information (Rost and Sander, 1994). The method has also been renamed several times, with the most recent version, ReProf, being available as part of the PredictProtein webserver (Yachdav *et al.*, 2014). PSIPRED is another common NN based prediction method with an approach similar to that of the PHDsec family (Jones, 1999). It uses sequence profiles

Table 1 A selection of secondary structure prediction methods discussed in this article

generated by PSI-BLAST (Altschul, 1997) as input to a NN with a sliding window of size 15, followed by a second smoothing NN with the same window size. The method has been continually updated since its first publication and the network architecture was recently improved (Buchan *et al.*, 2013). Finally, JPred4, a webserver built on the underlying Jnet also employs the two-level neural network methodology and has been updated many times since its first publication in 2000 (Drozdetskiy *et al.*, 2015; Cole *et al.*, 2008; Cuff and Barton, 2000). The method builds sequence profiles using PSI-BLAST as well as HMMER3, a hidden Markov model-based sequence search tool (Eddy, 2011), and trains two separate NN-pairs on the respective data. If these two models do not agree on a residue's prediction a third "jury" NN is used on the output of the previous two.

Prediction based on deep learning

SSpro5 is the most recent iteration of a secondary structure predictor which first performs a lookup of already known structures (Magnan and Baldi, 2014). The input sequence is compared to structures in the PDB using BLAST (Camacho *et al.*, 2009). If the resulting (local) alignments satisfy a set of similarity criteria the most common secondary structure class annotated in DSSP is used as the prediction for the respective residue. If no similar positions exist or the DSSP annotations do not form a majority, a neural network predictor is invoked to fill in predictions for the missing residues. This model consists of 100 bi-directional recurrent NNs. In contrast to the window-based feed-forward NNs covered so far, these networks can parse information of an arbitrarily large input sequence at once. In addition to the middle segment with the residue of interest and its neighbors, two other components of the network parse the rest of the sequence (Pollastri *et al.*, 2002). This could allow the recognition of global contacts which go beyond the correlations captured in the local window. The number of 100 networks result from the double cross-validation procedure which first splits the training set into 10 folds and then performs 10-fold cross-validation on each of them.

SPIDER2 is a deep-learning approach that combines the prediction of secondary structure elements with the prediction of solvent accessibility, backbone torsion angles and two more angles around the backbone C_α atoms (Heffernan *et al.*, 2015). The underlying idea is that these properties all correlate with each other to some degree. This makes the machine learning model aware of all classes at the same time which might improve prediction performance. SPIDER2 achieves this with an iterative approach: Given a PSI-BLAST PSSM of the input sequence and seven physicochemical indices, three NNs are separately trained for the prediction of secondary structure, solvent accessibility and the backbone angles. In the two following iterations, the input to each respective network is extended by the input from the other two networks. For example, predicted angles and solvent accessibility are used as input to the secondary structure predictor. In sum, this leads to three deep NN predictors with three hidden layers each. An improvement of the method using long short-term memory neural networks is currently in development.

Similar to SPIDER2, RaptorX Property is a webserver predicting several sequence features, including secondary structure and solvent accessibility (Wang *et al.*, 2016a,b). However, the prediction models are treated separately and do not interfere with each other. The authors use a deep convolutional neural field, which is the combination of a deep convolutional NN (DCNN) with seven hidden layers and a final output layer which together with the last hidden layer forms a conditional neural field (CNF). The rationale behind this design is that the DCNN can capture global relationships that go beyond the local window size of 11 residues while the final CNF learns the correlations between the secondary structure of adjacent residues. The input to the network is either just the sequence or a PSI-BLAST profile of that sequence.

Prediction based on other approaches

Frag1D performs secondary structure prediction based on a fragment matching approach (Zhou *et al.*, 2010). Given a query sequence, a sliding window of nine residues is used to find the 100 best-scoring fragments in a database of proteins with known structure. These 100 fragments are selected by comparing PSI-BLAST profiles and structural profiles between the input and database sequences. The structural profiles were created from so-called ShapeStrings which are defined based on the torsion angle pairs of the peptide bond. Same as for the direct sequence comparison, the database was searched for similar nine-residue stretches of ShapeStrings to build the structural profile which represents the conservation pattern in similar local structures. Further weighting the 100 fragments results in a preliminary secondary structure prediction. Given this prediction, the structural profile of the query sequence can now be computed and the whole process is repeated once to yield the final prediction.

s2D combines secondary structure prediction with the identification of disordered regions in proteins (Sormanni *et al.*, 2015). Such regions do not adopt a well-defined structure but instead fluctuate between different conformations (Habchi *et al.*, 2014). Typically, other methods extract secondary structure elements mostly from X-Ray crystallography structures through tools such as DSSP. In contrast, the s2D training data consists of annotations extracted from the chemical shifts of structures determined by nuclear magnetic resonance. In this way, all residues that show neither α -helical nor β -sheet properties can be considered as some form of disordered segments. Given these annotations, two NNs are trained with window sizes 11 and 15 but otherwise equal architecture. PSI-BLAST profiles are used as input to these networks. Next, a global network is trained with the same profiles and the output of the previous two networks resulting in a prediction of the mean secondary structure content in the whole sequence. Finally, the output of that network is combined with the initial inputs in a NN that smooths the prediction with a sliding window of five residues.

Estimates of Prediction Performance

As mentioned above in Section Assessing Secondary Structure Predictions two previous efforts for an automated independent assessment of secondary structure prediction are not maintained any longer. A related effort is CASP, a biannual challenge in which organizers collect

target proteins with known but unpublished structures (Moult *et al.*, 1995). The target sequences are given to the community who can submit their predictions for the proteins' structures. After the structures are publicly disclosed, the assessors evaluate the performance of the prediction methods on these previously unseen proteins. This enables an independent evaluation where neither the competition organizers nor the participating groups know the answer at the time of submission. CASP has a focus on protein 3D structure prediction but in the past also included an evaluation of secondary structure prediction methods. In CASP5 assessors found that helices are predicted better than sheets and that sequences with no homology to a solved structure were harder to predict (Aloy *et al.*, 2003).

Overall, methods seem to have approached a saturation point with only small improvements over the previous years. Therefore, public assessments were stopped. This means that current estimates of prediction performance are only regularly given by the authors of newly developed methods. Although these may have the best intentions in providing a fair comparison to previous approaches they typically focus only on the flawed Q_3 score and their reported numbers may still be biased to favor their own method – for example, by the selection of a specific dataset. Traditionally, reported performance values have often proven to be overestimated. Apart from over-training, over-estimates can also be caused by discovering completely new types of structures. Ultimately, one therefore has two ways to evaluate performance by either using old results from the “last public” assessments, thereby excluding all new methods, or using method-skewed values from publications, likely over-estimating performance for the methods reported. In this chapter, the second solution was favored. However, readers must be aware that the published evaluation numbers need to be viewed with substantial skepticism.

Keeping that in mind, the most recent methods such as s2D, JPred4, RaptorX Property and SSpro5, all report Q_3 values around 80–85%. These values seem realistic, given the last independently determined performance estimates along with the increase in database size. However, choosing the best method among them is impossible given their heterogeneous evaluation schemes.

Future Directions

Without any independent evaluations, it is hard to say whether the top has already been reached in secondary structure prediction. Reinstating secondary structure prediction evaluation through a CAMEO revival of approaches such as EVA and LiveBench may help greatly. Certainly, creating such an independent evaluation entity is far from trivial and great care will be necessary when choosing the underlying datasets and scoring procedure. Clearly the limit is not given by a Q_3 of 100%. Due to errors in experimental structure determination and since proteins are in motion, secondary structure assignments will always contain some amount of error (Kihara, 2005). For the time being, the main problem with the assessment of secondary structure prediction is that although the tools are essential as input to many subsequent “higher level” prediction methods, there are very few incentives to invest substantial efforts to doing evaluations right. At the same time, it has become so difficult to publish new prediction methods in this field that almost nothing less than the claim that the ultimate has been reached will even appear on the screen of experts. There are many good reasons for these two opposing realities but they clearly make it difficult to assess today's state-of-the-art. It also remains debatable whether there is a large value in another method that shows increasingly smaller improvements over the current state-of-the-art. With the recent advances in the prediction of 3D protein structures from sequence, the interest in dedicated secondary structure prediction methods may continue to fade. However, at this point they cannot be substituted yet, since the difference in runtime between the two fields reaches several orders of magnitude and secondary structure prediction methods currently still perform better than inferring helices and sheets from predicted 3D structures (Faraggi *et al.*, 2012).

Closing Remarks

Predicting protein secondary structure elements from sequence is among the oldest prediction approaches in the field. Benefitting from decades of work, predictions are now both fast and highly accurate although determining just how accurate exactly is proving hard.

Recently, interest in these predictions has decreased, partly owing to a focus shift towards higher goals such as the prediction of protein 3D structures. Nonetheless, the respective methods are still relevant and a crucial help in making sense of the current sequence data deluge.

Biographical Sketch

Jonas Reeb is a PhD student in the Rostlab at the Technical University of Munich, Germany (TUM). During his studies at TUM he has worked on evaluating methods for the prediction of transmembrane helices from sequence and on developing a crystallization propensity predictor for the NYCOMPS structural genomics pipeline. His doctoral thesis focusses on predicting the effects of sequence variants.

Burkhard Rost is a professor and Alexander von Humboldt award recipient at the Technical University of Munich, Germany (TUM). Rost was the first to combine machine learning with evolutionary information, and realized this combination to predict secondary structure. Since, his group has repeated this success in many other tools predicting aspects of protein structure and protein function. All tools are available through the first internet server in the field of protein structure prediction (PredictProtein), which has been online for over 25 years. Over the last years, the Rostlab has been shifting focus on the development of methods that predict and annotate the effect of sequence variation and their implications for precision medicine and personalized health.

Protein Three-Dimensional Structure Prediction

What is the Protein Structure Prediction Problem?

Predicting the Structure for a Protein Sequence

This article revolves around a simple question: “given an amino acid sequence, what is the folded structure of the protein?” (Fig. 1) Even though this seems like a simple question, the answer is far from straightforward. In fact, whether we can give an answer at all depends heavily on the sequence in question and available protein structures that can be used as modelling templates. While the number of structures deposited in the Protein Data Bank (PDB) (Berman *et al.*, 2000) continues to rise rapidly (see “Relevant Websites section”), the number of sequenced genes rises much faster. The large and widening gap between protein structures and sequences makes structure prediction an important problem to solve. Fortunately, recently developed methods can use these large resources of sequence data to increase the quality of some predictions. Here, we will give an overview of current structure prediction methods, and describe some tools that provide insight into how reliable the structure predicted will be.

The typical problem is that we want to generate a structural model for a protein with a sequence, but without an experimentally determined structure. In this article, we will build up a workflow for tackling this problem, starting from the easy options that, if applicable, are likely to generate a good structural model, and gradually working up to the more hypothetical options whose results are much more uncertain.

Another very important remark is in place here: the modelling strategy should depend heavily on what we want to do with the structure. Do we want to predict where the functional site of the protein is, whether a specific substrate binds, or if a certain residue may be exposed to the surface? These different questions imply a different degree of accuracy in the answer, and may lead to choices regarding technology and methods to carry out these predictions. It is important to keep in mind that one of the most important aspects of any scientific model is whether a research question may be answered with the model produced or not. Even if we do have an experimental structure available, some of these questions may not be straightforward to answer; we will come back to this issue later in the article.

Structure is More Conserved Than Sequence

Almost all structure prediction relies on the fact that, for two homologous proteins, structure is more conserved than (Bajaj and Blundell, 1984; see Fig. 2). The real power of this observation manifests itself when we turn this statement around: if two protein sequences are similar, these two proteins are likely to have a very similar structure. The latter statement has very important consequences. It means that if our sequence of interest is similar to a protein sequence with a known structure, we have a good starting point for a structural model. In such a scenario we use sequence similarity, suggesting an homologous relation between the proteins, to predict the structure. The vast majority of accurate structure prediction methods use structure conservation as an underlying principle; while methods that have been developed to deal with the more difficult modelling questions, exploit the sequence-structure-conservation relation in an advanced manner, as discussed towards the end of this article.

Terminology in Structure Prediction

Firstly, we should take care to lay down a good problem definition. Here we will generously borrow the nomenclature from the Critical Assessment of Protein Structures (CASP). CASP is a scientific competition, in which structure prediction groups and

Fig. 1 Structure prediction methods try to answer the question: Given an amino acid sequence, what is the folded protein structure?

Fig. 2 Protein structure is more conserved than sequence. Here the output of a structural alignment is shown on the left, created using *Chimera* (Molecular graphics and analyses were performed with the UCSF Chimera package. Chimera is developed by the Resource for Biocomputing, Visualisation, and Informatics at the University of California, San Francisco (supported by NIGMS P41-GM103311)). Reproduced from Pettersen, E. F., Goddard, T.D., Huang, C.C., *et al.*, 2004. UCSF Chimera – A visualization system for exploratory research and analysis. *Journal of Computational Chemistry*, 25 (13), 1605–1612. The structural alignment shows both proteins are highly similar; the RMSD is 2.3 over 144 aligned residues. Furthermore, the function of the two proteins, one from cattle (PDB:1L9H, light brown) and one from a archaeon (PDB:1GUE, light blue), is similar: both are light sensitive rhodopsins, used for vision and phototaxis, respectively. However, as can be seen in the sequence alignment on the right, the sequence identity is only 7%. This is lower than would be expected for any two random sequences. The alignment shown is based on the structural alignment on the left, and visualised using *JalView*. Reproduced from Waterhouse, A.M., Procter, J.B., Martin, D.M.A., Clamp, M., Barton, G.J., 2009. Jalview Version 2 – A multiple sequence alignment editor and analysis workbench. *Bioinformatics* 25 (9), 1189–1191.

structure prediction servers compete to predict the structure for an unknown sequence, that has been running since 1995 (Moult *et al.*, 1995). The sequence for which we will predict a structure is called the *target* sequence. If there is a suitable structure to build a model for our query sequence we call this structure a *template*, see also Fig. 3. Using the structure of the template and using the *sequence alignment* between the template and the target sequence, we can create one or more structural *models*: the predicted structure, for a target sequence. In CASP structural models from different prediction methods, are compared to the experimentally determined solution or target structure.

Different Classes of Structure Prediction Methods

We can classify structure prediction strategies into two categories of difficulty: template-based modelling, and template-free modelling (see Fig. 4). In the first case, it is possible to find a suitable template for the target sequence in the PDB, as a basis for the model, whereas for template-free modelling no such experimental structure is available. Note that it may not be trivial at all to find out in which of these two categories a structure prediction problem falls. Only if we can find a close homolog – based on sequence similarity – in the PDB we can be sure that a template based modelling strategy will suffice; this is also referred to as *homology modelling*. With a template, the constraints from the alignment between the model and the template sequence, in addition to the template structure, will give sufficient constraints to build a structural model for the target sequence. Even in this case, small missing substructures in the alignment, e.g., loops, may require a template-free modelling strategy.

If no close homologs are available in the PDB, we may need to use more advanced template finding strategies, such as remote homology detection or fold recognition methods.

If no suitable template is available, we will need to resort to a template-free modelling strategy. In the *ab initio* approach knowledge-based energy terms are used to generate structural models based on the sequence of the template alone. Small, suitable fragments, from various PDB structures are assembled to generate possible structural models. In some cases, we can find

Fig. 3 Terminology used in protein structure prediction. We start from our protein of interest (with no known structure): the target sequence. First step is find a matching protein: a template sequence with known structure; the template structure. We then create a template-target sequence alignment, and from this alignment create the structural model which is the solution structure for our target protein.

additional constraints, for example from experiments, such as NMR or cryoEM, or from contact prediction methods; in that case we have a much better chance of building a suitable model (Moult *et al.*, 2016). In fact, we could consider such constraints an alternative for the constraints provided by homology.

Lastly, several steps may be taken to refine the model, and to select the most likely model, from several model building attempts. Note that some structure prediction methods, may also include variations of model refinement and model selection steps higher up in the modelling workflow.

Domains

So far we have implied that we may follow the above strategy for an entire protein, however, this generally is not the case. In fact many proteins consist of multiple domains. If this is the case, it is wise to also run one or multiple disorder prediction methods on the target sequence; Any large regions (> 25 residues) predicted to be disordered should be left out for further structure prediction and template finding.

Most structure prediction methods only work well at the domain level. This means that a sequence first needs to be split in multiple domains, before we can start to make models. However, domain splitting is often ambiguous both given the sequence and the structure, while combining models built from various domains is far from trivial. In practice, this means that multiple templates might be necessary for a single target sequence and that it is difficult to resolve the orientation of the modelled domains with respect to each other.

Predicting the orientation for several domains is currently an unsolved problem, unless there is a suitable, homologous, template available – with the domains in the same orientation. In some cases, coarse constraints on the domain orientations such as data from small-angle scattering experiments, or distance restraints from NMR, chemical cross-links or co-evolution may help to put different homology models in the correct orientation.

Typically, it only makes sense to generate a model, be it template-based or template-free, for a single domain. In fact, in CASP model predictions are assessed per structural domain, separately. Therefore, it is essential to split the target sequence into its constituent domains – which is a non-trivial task, particularly if no homologous templates are available for each of the domains.

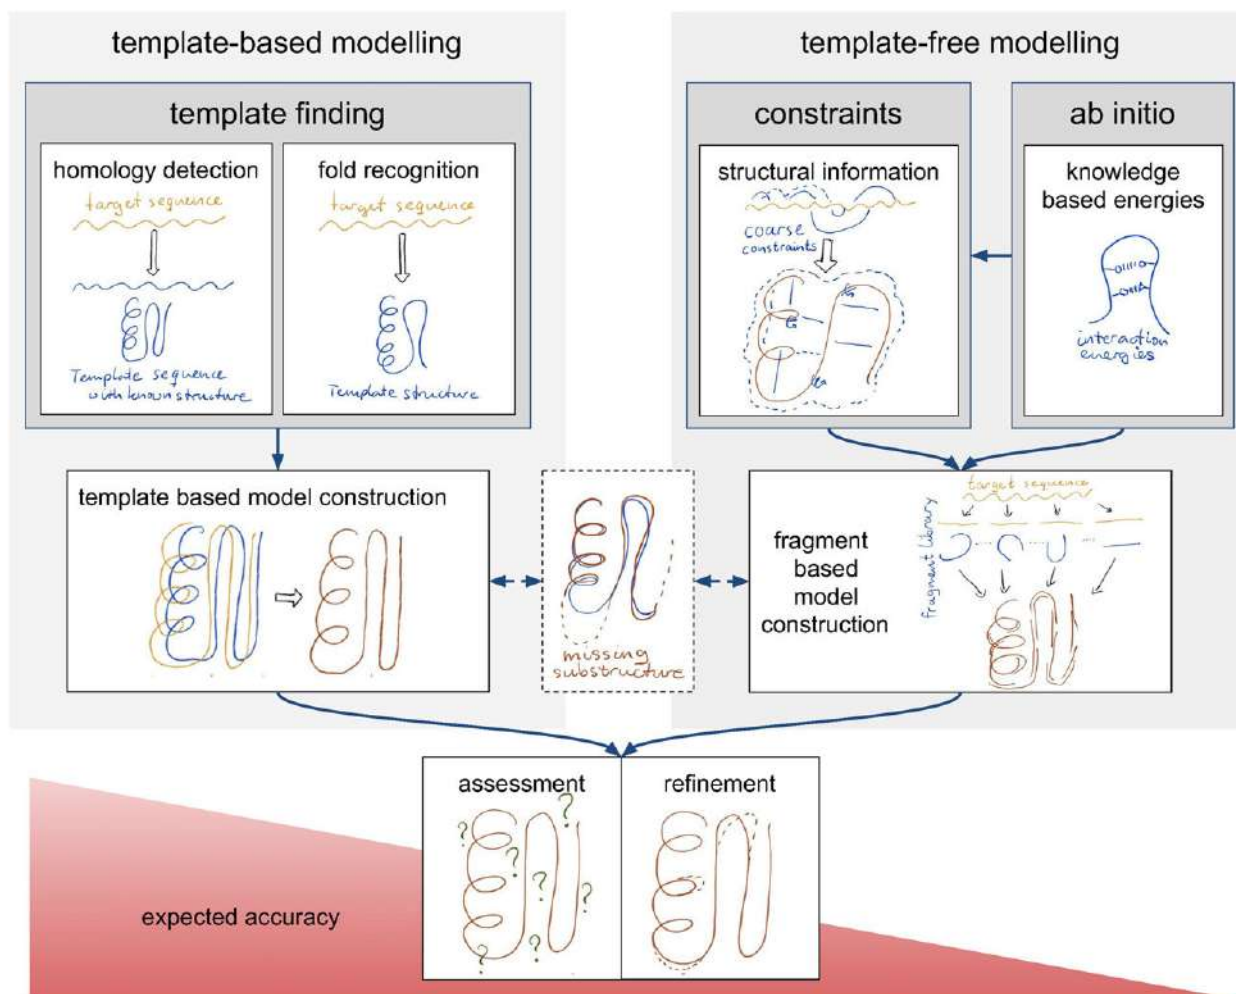

Fig. 4 Overview of Structure Prediction. Template-based modelling: a template is found on the basis of homology between the template and the target. Fold recognition: no obvious homologous structure can be found in the PDB, we need fold recognition methods to find a suitable template. Template-free modelling: no suitable template for protein domains can be found. Without template, we need to use a combination of coarse constraints from experiment or co-evolution analysis, and *ab initio* prediction. *Ab initio* methods typically work with taking fragment templates from various proteins, and assemble these into a model or decoy structure. Expected model accuracy declines from left to right: good accuracy is expected if based on homology; in contrast, *ab initio* modelling should only be considered if no other options remain.

Assessing the Quality of Structure Prediction Methods

Generally, as with any prediction problem, we can assess the quality of a prediction if we have a true answer to the question. Here, truth will be represented by an experimentally determined protein structure (of high quality). Fortunately, there are now (November 2017) over 120,000 deposited protein structures in the PDB (structures in the PDB: see “Relevant Websites section”). However, simply assessing how well a method performs over this set is problematic. The methods have been trained on structures contained in this data set, which implies there may be a strong bias in these methods to predict good models for sequences in their training dataset, and homologs of these sequences. In order to truly assess a method, a completely independent data set is required.

Critical Assessment of Protein Structure Prediction

Every other year CASP, a Critical Assessment of Protein Structure Prediction, provides such an independent validation benchmark. CASP is a blind test or competition: experimentalists provide sequences for which they know the structures will be solved imminently; modelling groups and servers try to predict the structure (Moult *et al.*, 1995). Once the structure is solved, the models can be evaluated using the solution structure of the target (see also Fig. 5).

CASP was started because the protein structure prediction problem was claimed to have been solved several times. The problem was, that algorithms were trained on databases that contained the structures that were evaluated in benchmarking tests. CASP overcomes this problem.

Fig. 5 Example of structural comparison for the target *T0886-D2* and two models submitted to CASP12. The top panel shows individual traces for all models generated for this target; the distance cutoff (vertical axis, in Å) is plotted against the fraction of residues (horizontal axis, in %) that can be aligned within this cutoff. The traces were obtained from predictioncenter.org/casp12. The dotted lines indicate the thresholds used in the GDT_TS (1, 2, 4, 8 Å) and GDT_HA (0.5, 1, 2, 4 Å) scores. Two models are highlighted in blue: a bad model (TS236; GDT_TS=18.90) on the left, and a good model (TS173; GDT_TS=51.97) on the right. Both model structures are also shown in the panels below in red, superposed onto the solution crystal structure in blue (PDB:5FHY). Structural superposition created using LGA at proteinmodel.org/AS2TS/LGA/. Reproduced from Zemla, A., 2003. LGA: A method for finding 3D similarities in protein structures. *Nucleic Acids Research*, 31 (13), 3370–4. 3D visualisation using *Chimera 1.11.2*. Reproduced from Pettersen, E.F., Goddard, T.D., Huang, C.C., *et al.*, 2004. UCSF Chimera – A visualization system for exploratory research and analysis. *Journal of Computational Chemistry*, 25 (13), 1605–1612.

Note that the very first step in any practical structure prediction approach, should be to inspect the results from the latest CASP round (Moult *et al.*, 2016) via the CASP website (CASP website: see “Relevant Websites section”) to see what the state of the art methods are, and what their expected performance is.

Root-Mean-Square Deviation (RMSD)

If we want to assess the quality of a method, we need to measure the quality of the predictions made by the method. Hence, one would like to structurally compare atomic coordinates of the model and of the solution structure, and quantify the (dis)similarity.

The problem of comparing a model to a solution structure, is less difficult than the comparison between two homologous protein structures. This is because the alignment is trivial: the model has the same sequence as the solution structure; we know which residues, and atoms should correspond in the two structures.

The easiest way to compare structures, is to calculate the Root-Mean-Square Deviation (RMSD) after a structural superpositioning (Marti-Renom *et al.*, 2009). The superpositioning is required, because two arbitrary structures will typically not be positioned at coordinates suitable for comparison; first a translation and rotation needs to be applied to one of the two structures, to minimise the RMSD; the resulting RMSD after superpositioning can be used as a dissimilarity measure.

The Root-Mean-Square Deviation (RMSD) calculates the squared difference between two sets of atoms, and can be defined as follows:

$$\begin{aligned} \text{RMSD}(v, w) &= \sqrt{\frac{1}{n} \sum_{i=1}^n \|v_i - w_i\|^2} \\ &= \sqrt{\frac{1}{n} \sum_{i=1}^n (v_{ix} - w_{ix})^2 + (v_{iy} - w_{iy})^2 + (v_{iz} - w_{iz})^2} \end{aligned}$$

Here, v_i is the position vector of i^{th} atom of structure v ; w_i is the position vector of i^{th} atom of structure w ; and n is the total number of aligned atoms.

The RMSD takes the average over all aligned pairs. In protein structures typically one representative atom per residue is chosen, such as C α or C β .

GDT – Global Distance Test

If a model gets a loop very wrong, it tends to stick out and can be positioned very distant from the true structure, even though the remaining structure may be reasonably accurate. This partial outlier weighs heavily on the average distance calculated. Hence the RMSD is oversensitive to such outliers.

The global distance test total score (GDT_TS) is a more robust structural similarity measure that is well defined given an alignment between two structures. The key idea is to count the number of residues that can maximally be fitted within a certain distance cutoff, see also Fig. 5. The GDT score will therefore produce a percentage. In the formula below, the final score is the average over four different distance cutoffs (1, 2, 4, 8 Å).

$$\text{GDT_TS} = \frac{1}{4} \sum_{v=1,2,4,8\text{\AA}} \frac{G(v)}{t} \quad (1)$$

Here, $G(v)$ is the number of aligned residues within given RMSD cutoff v (in Ångstrom – 10^{-10}m) and t is the total number of aligned residues. A related score called GDT_HA was introduced in CASP some time ago (Read and Chavali, 2007) using stricter distance cutoffs (0.5, 1, 2, 4 Å), to cater for targets in the template-based modelling category where very high accuracies can be realized:

For a typical “difficult” CASP target no model even comes close to the experimentally solved structure; typical results would be similar to the left-most model in Fig. 5. If we have a look at the latest CASP results one will see that a performance of $\text{GDT_TS} < 20\%$ is not an exception. In other words, the protein structure prediction problem has NOT yet been solved, especially not if one considers targets without a good template structure.

How Difficult is it to Predict?

Overall, if one can find a good template, the quality of the predicted model will be relatively good. CASP results show that for homology modelling based on close homologs, it is possible to obtain models similar to the experimentally determined structure (Moult *et al.*, 2016). The modelled structure will typically have a good accuracy for the regions that can be well aligned between the target and template (using the sequences). The top two bars in Fig. 6 shows that one may expect the majority of such models to be accurate for $> 50\%$ of their residues. Gaps in an alignment will typically lie in loop regions of a structure and are more difficult to model. So, if we are interested in a large loop region that is not present in our template, we still may not be able to answer our scientific question with the resulting model structure (Moult *et al.*, 2016).

If no acceptable template can be found, the chances of successfully answering our scientific question will become very low. As a last resort, *ab initio* modelling can provide us with structural models. Typically, *ab initio* methods use very small templates from various proteins (see Fig. 4). The state of the art is that on average one may expect to find one structure that looks somewhat like the solution structure for the target among the top five or ten models (Moult *et al.*, 2016). However, be aware that the best model is typically not recognised as being the best through the scores of the prediction program. In Fig. 6 one sees that very clearly in the bottom few bars: without template, even with predicted contacts, one may have less than 20% of the structure correct in the majority of models; even in the best cases at most 40% of the residues are modelled accurately.

For Which Gene Sequences can we Predict a Three-Dimensional Structure?

If and only if there is a structure of a homologous protein present in the PDB, it is possible to generate a structural model of reasonable accuracy. Based on this notion, we can estimate for which (fraction of) gene sequences it is possible to predict a structure. This way it

Fig. 6 Distribution of GDT_TS scores for the different model categories in CASP11 for template-based, template-free with contact information and template-free. The legend coloring corresponds to the GDT_TS scores, the bars indicate the fraction of models in each GDT_TS range for the six categories (GDT_TS scores for Modi *et al.* were estimated from the reported GDT_HA scores using their Fig. 4(A)). “Outliers” targets have unusually high GDT_TS due to being very short (~50 residue) with extended structures. Targets selected for server prediction (top bar) were considered easier than those for human prediction (second from top), average sequence identity was 26% vs. 20%, respectively. It is clear that overall prediction accuracy sharply declines going down this list of categories. For template-free modelling, the quality of contact information used is crucial. Experimental information (from chemical cross linking or simulated NMR) can give reasonable models. Predicted contacts do not guarantee that an acceptable model can be obtained, but without even predicted contacts, more than two-thirds of models are at most 20% correct. Reproduced from Modi, V., Xu, Q., Adhikari, S., Dunbrack, R.L., 2016. Assessment of template-based modeling of protein structure in CASP11. *Proteins: Structure, Function, and Bioinformatics* 84 (S1), S200–S220. Kinch, L.N., Li, W., Monastyrskyy, B., Kryshtafovych, A., Grishin, N.V., 2016a. Assessment of CASP11 contact-assisted predictions. *Proteins: Structure, Function, and Bioinformatics* 84 (S1), S164–S180. Kinch, L. N., Li, W., Monastyrskyy, B., Kryshtafovych, A., Grishin, N.V., 2016b. Evaluation of free modeling targets in CASP11 and ROLL. *Proteins: Structure, Function, and Bioinformatics* 84 (S1), S51–S66.

has been estimated that for a about 44% of residues in Eukaryotic gene sequences, we cannot yet make a homology model, and 15% of these residues lie within a gene for which we can not make a homology model for a single domain (Perdigão *et al.*, 2015). Especially membrane proteins are underrepresented in the PDB, due to the experimental difficulty of determining these structures. Note that these residues, may also lie in natively disordered regions (see also Section “Is there such a Concept as a Single Native Fold?”).

Similarly, it is possible to predict the range of protein structures present in an organism, based on the gene sequences identified in their completed genome. Gene prediction over a large number of organisms has revealed that there is a subset of protein structures that is present in nearly all organisms, for example TIM-barrels or Rossmann-folds (Abeln and Deane, 2005; Edwards *et al.*, 2013). Nevertheless, there is also a group of structures that is extremely lineage specific. It is to be expected that for this group of proteins many new structures remain to be discovered. This also implies that it will remain difficult to find suitable templates for homology modelling for these lineage-specific protein families.

How Accurate do we Need to be?

We already mentioned that we may approach the modelling of a protein structure of interest differently, depending on the biological question we want to ask, e.g., which residues are likely to be crucial for the functioning of the protein. Sometimes an answer to the research question may be possible in a simpler way, without full-scale prediction of the protein structure, e.g., by direct prediction of the impact of certain mutations or of protein-protein interaction sites. Examples of fully-automated webserver that do just that, are HOPE- (Venselaar *et al.*, 2010) and SeRenDIP (Hou *et al.*, 2017). In some cases, a rough homology model inspires the understanding of experimental results, spurring forward the project and eventually ending with crystal structures highlighting the protein function (in this case, protein-protein interactions) of interest (e.g., De Vries-van Leeuwen *et al.*, 2013). Also, specifically for enzymes, such as for example cytochromes P450, modelling of the protein structure should be done in combination with that of the ligand (de Graaf *et al.*, 2005).

In CASP11, three functional aspects, selected on being amenable to qualitative evaluation, were explicitly scored: multimeric state, (small) ligand binding, and mutation impact. Targets were selected that in solved crystal structure were dimeric, or had a ligand bound, or where from the crystallographers or in literature interest was expressed for evaluating mutants (Huwe *et al.*, 2016).

For prediction of dimer structures, only in two out of ten cases a dimer model with reasonable accuracy could be generated for the majority of monomer model structures (Huwe *et al.*, 2016). In the critical assessment of prediction of protein interaction (CAPRI), between 30%–80% of models were of ‘acceptable’ or ‘medium’ quality for easy dimer targets, while for harder targets (difficult dimers, multimers and heteromers), this fraction dropped to below 10% (Lensink *et al.*, 2016). Encouragingly, it was seen that also structure models of lower quality could sometimes lead to acceptable or even medium quality models of the bound proteins (Lensink *et al.*, 2016).

For ligand binding, it was found that the accuracy of even the best models (~ 2 Å) was not good enough for accurate ligand docking; the best ligands were around 5 Å RMSD (Huwe *et al.*, 2016). Something similar was found for mutation impact prediction; for most targets, model accuracy did not correlate with accuracy of impact prediction (Huwe *et al.*, 2016). Apparently, either homology models are not yet accurate enough for this purpose, or methods are tuned to particular characteristics of crystal structures.

Template Based Protein Structure Modelling

In the next two sections, we will in detail discuss first template-based and then template-free modelling. An overview of protein structure modelling, including both template-based and template-free modelling is given in Fig. 7; see also Fig. 3 for the terminology used.

Fig. 7 Flowchart of protein three-dimensional structure prediction. It starts at the top left with the target protein sequence of interest, and ends with a predicted 3D structure at the bottom. Depending on the availability of a homologous template, a suitable fold, or coarse/experimental constraints, different options are available, with sharply decreasing expected model accuracy for each step. Homology-based models (far left) are most accurate, while ab-initio modelling (far right) is notoriously unreliable. Template-based (by homology or fold recognition) models require an alignment with the target sequence, from which the initial model will be built. Course constraints may sometimes be incorporated in this stage. The raw model may need to be completed by separate modelling of the missing substructures. Template-free modelling can benefit greatly if such constraints are available, if not the only sources left are fragment libraries and knowledge-based energy functions. The model, whether template-based or -free, is usually refined until a desired level of (estimated) quality is reached to produce the final predicted structure for our target protein sequence of interest.

Homology Based Template Finding

Homology modelling is a type of template based modelling with a template that is homologous to the target protein. As mentioned before, homology modelling works well, because structure is more conserved than sequence (Bajaj and Blundell, 1984; see Fig. 2). Typically, we will use a sequence-based homology detection method, such as BLAST, to search for homologous protein sequences in the full PDB dataset. If we find a sequence that has significant sequence similarity to the full length of our target sequence we have found a template. Of course it is possible that a template only covers part of the target sequence, see also Section “Domains” on domains above.

If a simple BLAST search against the PDB gives no good results we may need to start using alignment methods that can detect more distant homologs based on sequence comparison, such as PSI-BLAST or HMMs. PSI-BLAST uses hits from a previous iteration of BLAST to create a profile for our query sequence (Altschul *et al.*, 1997). This allows successive iterations to give more weight to very conserved residues, allowing to find more distant homologs. Even more sensitive homology detection tools typically consider sequence profiles of both the query and the template sequence, and try to align or score these profiles against each other (Petrokovski, 1996), with more recent implementations including Compass (Sadreyev and Grishin, 2003), HMMer (Finn *et al.*, 2011) and HHpred (Söding *et al.*, 2005). Profile-profile matching is known to increase detection of evolutionary sequence signals, leading to optimised alignment or sensitive sequence searching (Wang and Dunbrack, 2004). Note that to make full use of such methods it is important that the searching profiles are generated using extended sequence databases (so not just on the PDB). The evolutionary sequence profiles used in these methods can ensure that the most conserved, and therefore structurally most important, residues are more likely to be aligned accurately.

Once we have a good template, and an alignment of the target sequence with the template structure, we can build a structural model; this is called homology modelling in cases of clear homology between the target and the template.

Fold Recognition

If no obvious homologs with a known structure can be found in the PDB, it becomes substantially more difficult to predict the structure for a sequence. We may then use another trick to find a template: remember that the template does not only have a sequence, but also a structure. Therefore, we may be able to use structural information in this search. Fold recognition methods look explicitly for a plausible match between our query sequence and a *structure* from a database. Typically, such methods use structural information of the putative template to determine a match between the target sequence and the putative template sequence and structure.

Note that, in contrast to homology-based template search, it is not strictly necessary for a target sequence and a template sequence to be homologous – they may have obtained similar structures through convergent evolution. Therefore some fold recognition methods are trained and optimised for detection of structural similarity, rather than homology. In fact, for very remote homologs we may not be able to differentiate between convergent and divergent evolution. For the purpose of structure prediction this may not be an important distinction, nevertheless divergent evolution, i.e., homology through a shared common ancestor, invokes the principle of structure being more conserved, giving more confidence in the final model.

Threading is an example of a fold recognition method (Jones *et al.*, 1992). The query sequence is threaded through the proposed template structure. This means structural information of the template can be taken into account when score if the (threaded) alignment between the target and the potential template is a good fit. Typically threading works by scoring the pairs in the structure that make a contact, given the sequence composition. A sequence should also be aligned (threaded) onto the structure giving the best score. Scores are typically based on knowledge based potentials. For example, if two hydrophobic residues are in contact this would give a better score than a contact between a hydrophobic and polar amino acid. Note that threading does not necessarily search for homology. Threading remains a popular fold recognition methods, with several implementations available (Jones *et al.*, 1992; Zhang, 2008; Song *et al.*, 2013).

Another conceptually different fold recognition approach is to consider that amino-acid conservation rates may strongly differ between different structural environments. For example, one would expect residues on the surface to be less conserved, compared to those buried in the core. Similarly, residues in a α -helix or β -strand or typically more conserved than those in loop regions. In fact, the chance to form an insertion or deletion in a loop regions is seven times more likely than within (other) secondary structure elements. Since we know the structural environment of the residues for the potential template, we can use this to score an alignment between the target sequence and potential template sequence. FUGUE is a method that scores alignments using structural environment-specific substitution matrices and structure-dependent gap penalties (Shi *et al.*, 2001).

Generating the Target-Template Alignment

Once a suitable template has been found, one can start building a structural model. Typical model building methods will need the following inputs: (1) the target sequence, (2) the template structure, (3) sequence alignment between target and template and (4) any additional known constraints. The output will be a structural model, based on the constraints defined by the template structure and the sequence alignment.

Here, it is important to note that the methods that recognize good potential templates, are not necessarily the methods that will produce the most accurate alignments between the target and template sequence. As the final model will heavily depend upon the

alignment used, it is important to consider different methods, including for example structure and profile based methods, multiple sequence alignment programs or methods that can include structural information of the template in constructing the alignment. Examples of good sequence-based alignment methods, which can also exploit evolutionary signals and profiles, are *Praline* (Simossis *et al.*, 2005) and *T-coffee* (Notredame *et al.*, 2000). The T-coffee suite also includes the structure-aware alignment method *3d-coffee* (O'Sullivan *et al.*, 2004). Some aligners are context-aware, taking into account for example secondary structure (Simossis and Heringa, 2005) or trans-membrane (TM) regions explicitly (Pirovano *et al.*, 2008, 2010; Floden *et al.*, 2016), which are useful extension as TM proteins are severely underrepresented in the PDB. Of particular interest to the general user are automated template detection tools such as HHpred (Söding *et al.*, 2005). Bawono *et al.* (2017) give a good and up-to-date overview of multiple sequence alignment methodology, including profile-based and hidden-Markov-based methods.

Moreover, once a first model is created, it may be wise to interactively adapt the alignment, based on the resulting model, which might lead to an updated model. This procedure may also be carried out in an interactive fashion.

Generating a Model

Here we consider the *MODELLER* software to generate template based alignments (Sali and Blundell, 1993), which is one of several alternative approaches to construct homology models (Schwede *et al.*, 2003; Zhang, 2008; Song *et al.*, 2013). Firstly, the known template 3D structures should be aligned with the target sequence. Secondly, spatial features, such as C α -C α distances, hydrogen bonds, and mainchain and sidechain dihedral angles, are transferred from the template(s) to the target. *MODELLER* uses "knowledge based" constraints. The constraints are based on the template distances, the alignment, but also on knowledge- Based energy functions (probability distribution). The constraints are optimised using molecular dynamics with simulated annealing. Finally, a 3D model can be generated by satisfying all the restraints as well as possible.

Loop or Missing Substructure Modelling

We now have a model for all the residues that were aligned well between the template and the target. The remaining substructure(s), that are not covered by the template, will show as gaps in the alignment between target sequence and template. 'Loop modelling' is used to determine the structure for these missing parts. Loop models are typically based on fragment libraries, knowledge based potentials and constraints from the aligned structure. This problem is in fact closely related to the template-free modelling procedure, as we need to generate a structure without a readily available template (template-free approaches are discussed in more detail in the next section). In CASP11, consistent refinement overall as well as for loop regions was achieved; the limiting factor for effective refinement was concluded to be the energie functions used, in particular missing physicochemical effects and balance of energy terms (Lee *et al.*, 2016).

Template-Free Protein Structure Modelling

What if no Suitable Template Exists?

If on the other hand, no suitable template is available for our target protein of interest, we will need to follow a 'template-free' modelling strategy. Without a direct suitable template, we need an *ab initio* strategy that can suggest possible structural models based on the sequence of the template alone. In this case, we need to resort to fragment based approaches. Here small, suitable fragments, from various PDB structure, are assembled to generate possible structural models. As the fragments are typically matched using sequence similarity, one may even consider this as template based modelling at a smaller scale. However, since the sequence match is based on a limited number of residues, this would not generally imply a homologous relation between the fragment template and the target sequence. It is also important to note that this type of *ab initio* modelling is still "knowledge based": the structural models are generated from small substructures present in the PDB, assessed by energy scoring functions generated by mining the PDB. In other words, these model are not based on physical principles and physico-chemical properties alone. This also means, that such models are likely to share any of the biases that are present in the PDB, such as lack of trans-membrane proteins and absence of disordered regions.

Generating Models From Structural Fragments

Here we follow the keys ideas in the *Rosetta* based *ab initio* modelling suite (Simons *et al.*, 1999). Quark, another fragment-based approach provides a similar performing alternative (Xu and Zhang, 2012). The overall approach is to split the target sequence into 3 and 9-residue overlapping sequence fragments, i.e., sliding windows, and find matching structural fragments from PDB.

A fragment library is generated by taking 3 and 9-residue fragments from the PDB and clustering these together into groups of similar structure. For each fragment in the database sequence profiles are created. These profiles subsequently are used to search for suitable fragments for our query/target sequence, as we only have sequence information (see Fig. 8 on the left-hand side).

The target sequence also will be split into 3 and 9-residue overlapping sequence fragments. These target sequence fragments are then matched with the structural PDB based fragment library using profile-profile matching. Note that this procedure will generate multiple fragments for each fragment window in the sequence. The fragment windows on the sequence typically also overlap (see Fig. 8 middle panel).

Fig. 8 Overview of the fragment-based modelling strategy. A library of structure fragments was created once from the PDB; all small 3-residues and larger 9-residue fragments are collected and clustered. A target sequence of interest is also separated into 3- and 9-residue sequence fragments. For each of these, a profile-profile search is performed to find matching fragments from the fragment library; typically for each target fragment, multiple hits with different structure are retrieved. This collection of fragments of alternate structure are then assembled through a Monte Carlo algorithm into a large set of possible structures, called 'decoys'. Using knowledge-based potentials and overall statistics, from the decoy set, a final selection of model structures is made.

Fragment Assembly Into Decoys

The above scenario leads to many possible structural fragments to cover a sequence position. To find the best structural model is a combinatorial problem in terms of fragment combinations, see Fig. 8 top right. A Monte Carlo algorithm is used to search through different fragment combinations. Good combinations are those that give a low energy. Each MC run will produce a different model, since it is a stochastic algorithm. Note that to be able to optimise a model, we need a scoring function. A knowledge based energy function is used, including the number of neighbours, given amino acid type, residue pair interactions, backbone hydrogen bonding, strand arrangement, helix packing, radius of gyration, Van der Waals repulsion. These are all terms that are relatively cheap to compute when a new combination of fragments is tried. The structural model is optimised by slowly lowering the MC temperature – this is also called simulated annealing. The generated models are called 'decoys'.

Thereafter, decoys are refined using additional Monte Carlo cycles, and a more fine-grained energy function including: backbone torsion angles, Lennard-Jones interactions, main chain and side-chain hydrogen bonding, solvation energy, rotamers and a comparison to unfolded state.

Finally, the most difficult task is to select, from all the refined decoys, a structure that is a suitable model for the target sequence, see Fig. 8 bottom right. Again, using a more detailed, knowledge-based energy function, decoys can be scored to assess how 'protein-like' they are. Such a selection procedure may get rid of very wrong models. However, selecting the best model, without any additional information (from for example experiments or co-evolution-based contact-prediction), is likely to lead to poor results, as is shown in Fig. 6.

Constraints From Co-Evolution Based Contact Prediction or Experiments

As already mentioned, valuable additions to the modelling process are coarse constraints from experimental data or contact prediction. Experimental data from NMR and chemical cross-linking can yield distance restraints that are particularly useful in the template-free modelling to narrow down the conformational space to be searched; still average accuracy of models produced remains extremely limited, (see Fig. 6; Kinch *et al.*, 2016a). Other sources of information are contours or surfaces that can be obtained from cryo-EM, or small angle scattering experiments, either with electrons, neutrons, or x-ray radiation. However, since these techniques are employed mostly for elucidating larger macromolecular complexes, they are considered out of scope for the current article.

Of more general applicability may be methods for predicting intra-protein residue contacts; the main approach currently is based on some form of co-evolution information obtained by direct-coupling methods from 'deep' alignments (Marks *et al.*, 2011; Jones *et al.*, 2012; Morcos *et al.*, 2011). Depth here signifies the amount of sequence variation present in the alignment in relation

to the length of the protein (the longer the protein, the more variation is needed). [Ovchinnikov et al. \(2017\)](#) expresses this as the *effective protein length*: $Nf = N80\%ID/\sqrt{l}$ where l is the protein length, and $N80\%ID$ the number of cluster at 80% sequence identity. They showed that Nf can be greatly enhanced by the use of metagenomic sequencing data, and that this leads to a marked improvement in model quality, and estimate that this would triple the number of protein families for which the correct fold might be predicted ([Ovchinnikov et al., 2017](#)). [Wuyun et al. \(2016\)](#) investigated ‘consensus’-based methods, which combine both direct-coupling and machine-learning approaches, and find that the machine-learning methods are less sensitive to alignment depth and target difficulty, which are crucial factors for success for the direct-coupling methods.

Selecting and Refining Models From Structure Prediction

Once we have created (several) models, we need to assess which model is the best one. Typically this can be done by scoring models on several properties using model quality assessment programs and visual inspection with respect to “protein like” features. Moreover, if any additional knowledge about the structure or function of our target protein is available, this may also help to assess the quality of the model(s). In addition, one may in some cases want to improve a model, or parts of it; this is called model refinement.

Model Refinement

For many years in CASP, model refinement was a no-go area; the rule of thumb was: build our homology model and do not touch it! An impressive example of the failure of refinement methods was shown by the David Shaw group, who concluded that “simulations initiated from homology models drift away from the native structure” ([Raval et al., 2012](#)). Since CASP10 in 2014 ([Nugent et al., 2014](#)) and continuing in the latest CASP11, there is reason for moderate optimism. General refinement strategies report small but significant improvements of 3%–5% over 70% of models ([Modi and Dunbrack, 2016](#)). Interestingly, and in stark contrast to the earlier results by [Raval et al. \(2012\)](#), the average improvement of GDT_HA using simulation-based refinement now also is about 3.8, with an improvement (more than 0.5) for 26 models ([Feig and Mirjalili, 2016](#)). For five models, the scores became worse (by more than 0.5), and another five showed no significant change. Particularly, for very good initial models (GDT_HA > 65), models were made worse. Moreover, they also convincingly showed that both more and longer simulations consistently improved these results; note however that protocol details such as using C α restraints, are thought to be the limiting factor ([Feig and Mirjalili, 2016](#)), as already used previously (e.g., [Keizers et al., 2005](#); [Feenstra et al., 2006](#)), and replicated by others (e.g., [Cheng et al., 2017](#)). Most successful refinement appears to come from correctly placing β -sheet or coil regions at the termini ([Modi and Dunbrack, 2016](#)).

Model Quality Assessment Strategies

It may be generally helpful to compare models generated by different prediction methods; if models from different methods look alike (more precisely if the pair has a low RMSD and/or high GDT_TS) they are more likely to be correct. Similarly, templates found by different template finding strategies, found for example both by homology sequence searches and fold recognition methods are more likely to yield good modelling results ([Moult et al., 2016](#); [Kryshtafovych et al., 2016](#)). Such a consensus template is generally more reliable than the predictions from individual methods – especially if the individual scores are barely significant. Lastly, one can consider biological context to select good models.

Whether a model is built using homology modelling, fold recognition and modelling or *ab initio* prediction, all models can be given to a Model Quality Assessment Program (MQAP) for model validation. A validation program provides a score predicting how reliable the model is. These scores typically take into account to what extent a model resembles a “true” protein structure. The best performing validation programs take a large set of predicted models, and indicate which out of these is expected to be the most reliable.

Validation scoring may be based on similar ideas as validation for experimental structures or may be specific to structure prediction. For example, it can be checked if the amount of secondary structure, e.g., helix and strand vs. loop, has a similar ratio as in known protein structures; if a model for a sequence of 200 amino acids does not contain a single helix or β -strand, the model does not resemble true protein structures, and is therefore very unlikely to be the true structural solution for the sequence. A similar type of check may be done for the amount of buried hydrophobic groups and globularity of the protein.

Different models may also be compared to each other. One trick that is commonly used, is that if multiple prediction methods create structurally similar models, these models are more likely to be correct. Hence, a good prediction strategy is to use several prediction methods, and pick out the most consistent solution. A pitfall here is that if all models are based on the same, or very similar, templates, they will look similar but this may not indicate the likelihood of them being correct.

Secondary Structure Prediction

Secondary structure prediction is relatively accurate, and is in fact much easier to solve than three-dimensional structure prediction, see, e.g., the review by [Pirovano and Heringa \(2010\)](#). The accuracy of assigning strand, helix or loops to a certain residue can go up

to 80% with the most reliable methods. Typically such methods use (hydrophobic) periodicity in the sequence combined with phi and psi angle preferences of certain amino acid types to come to accurate predictions. The real challenge lies in assembling the secondary structure element in a correct topology. Nevertheless, secondary structure prediction may be used to assess the quality of a model built with a (tertiary) structure prediction method. Many (automated) methods also incorporate secondary structure information during (Simossis and Heringa, 2005), homology detection (Söding *et al.*, 2005; Shi *et al.*, 2001) and contact prediction (Terashi and Kihara, 2017; Wang *et al.*, 2017).

Is There Such a Concept as a Single Native Fold?

Before we conclude, we should consider a more physical description of protein structure. In fact, protein folding from a physical point of view is a very interesting process: given a sequence, a protein tends to fold always, and exactly into the same functional structure. In material design, it is extremely difficult to mimic such high specificity. The apparent observation of folding specificity also leads to the question, is there such a concept as a single native fold? Or, more pragmatically, is sequence-to-structure truly a one-to-one relation?

In fact, if one wants to start making quantitative predictions, such as the stability of a protein fold, or the binding strength between two proteins in terms of free energy, it is much more helpful to think in ensembles of structural configurations for a protein sequence (e.g., May *et al.*, 2014; Pucci *et al.*, 2017). The probability to find a protein in a specific ensemble of structural configurations will depend on conditions such as the presence or absence of binding partners, the pressure, the pH or the temperature (e.g., van Dijk *et al.*, 2015, 2016). There are a few specific cases, common cases, for which even the functional or biologically relevant structural ensembles do not resemble a single globular folded structure.

Disordered Proteins

Not all proteins fold into single configurations, some proteins stay natively unfolded, i.e., they can take up a large variety of more extended, and very different configurations (Uversky *et al.*, 2000; Mészáros *et al.*, 2007). Some disordered regions contain elements that do form stable structures upon binding. The regions that remain disordered are thought to be important to prevent aggregation within the cell (Abeln and Frenkel, 2008). Missing residues in X-ray structures are typically removed for crystallization; for this reason disorder prediction methods have been developed. Disordered regions are relatively easy to predict in protein sequences just like secondary structures; broadly speaking, prediction can be based on the large amount of charged/polar (hydrophilic) amino acids in combination with the presence of amino acids that disrupt the secondary structure (proline and glycine) in these regions (Oldfield *et al.*, 2005; Wang *et al.*, 2016). We know sequences of many proteins contain large disordered segments (33% of eukaryotic, 2% archaeal, and 4% bacterial proteins; Ward *et al.* (2004)).

Allostery and Functional Structural Ensembles

It is important to realize that one protein, typically, does not correspond to one defined three-dimensional structure. Disordered regions or proteins are one particularly salient case, but also proteins which fold into specific three-dimensional configurations, may exist in multiple functional states each with a specific structure. The biological question of interest dictates which state is relevant. Most proteins have only been crystallized in one particular state, and often it is not known to which biological condition this crystal structure may correspond. One may have cases where a homology model of the relevant state may be preferred over a crystal structure of a different or unknown state (e.g., de Graaf *et al.*, 2005).

Amyloid Fibrils

Lastly, we should consider a competing state of folded proteins: the aggregated state, where multiple peptide chains clog together in fibrillar structures or amorphous aggregates. Amyloid fibres are formed by β -strands formed between different protein or peptide (small protein) chains. Fibril formation is associated with various neurodegenerative diseases, such as Alzheimer's, Creutzfeldt-Jakob and Parkinson's (Chiti and Dobson, 2006). In fact, the fibrillar state is more favorable than the state of separately folded structures for several protein types. The general cellular toxicity of such aggregates, puts evolutionary pressure on avoiding structural characteristics on the surface of proteins; hence it is extremely rare to observe solvent accessible β -strand edges or large hydrophobic surface patches (Richardson and Richardson, 2002; Abeln and Frenkel, 2011). The propensity proteins have to form Amyloid fibrils is relatively easy to predict (Graña-Montes *et al.*, 2017). However, reference databases are still small so it is difficult to verify such methods.

Glossary

Clashscore Representative score for validating the quality of a molecular structural model, that is, the number of too-close atom–atom contacts per 1000 atoms in the model.

Density map Electron density maps and EM maps are maps of a material's density; they are direct outputs of X-ray crystallography and electron microscopy, respectively, and models of molecular structures are fitted into them.

Distance constraint Nuclear magnetic resonance spectroscopy generates a list of atom–atom distances in a molecule, which are used to determine the molecule's conformation.

Electron microscopy Method to determine a structure by observing molecular images with an electron microscope and projecting a density map of the molecules.

Nuclear magnetic resonance spectroscopy Method to determine a structure by irradiating radioisotope-labeled samples with microwaves and evaluating interatom distances and bond angles constraints.

Ramachandran plot Two-dimensional plot for validating a protein main-chain conformation in which main-chain torsion ϕ angles are plotted against ψ angles, and the plot area is divided into allowed and disallowed regions.

RMSZ score Representative score for validating the quality of a molecular structural model by the Z-score deviations of atom bond lengths and angles of models from canonical values of reference structures.

X-ray crystallography Method to determine a structure by measuring X-ray diffractions from crystals and synthesizing an electron density map of molecules.

Introduction

Proteins are the major working biological molecules in the cell. Proteins fold into three-dimensional (3D or tertiary) structures under natural conditions. Knowing the 3D structures is required to understand the chemical and physical bases of their functions. It is also important that most biological molecules work in collaboration by forming complexes (supramolecules) of subunits including proteins, nucleic acids, carbohydrates, lipids, and small molecules. Recently, analysis of supramolecules is increasingly important in structural biology, and many innovative improvements have been made in the methods of structural analyses and validations for application to larger supramolecules.

Experimental Methods to Determine Structure

There are three major experimental methods to determine the structure of biological molecules: X-ray crystallography (XRC or often referred to as XP, which stands for protein crystallography) (Drenth and Mesters, 2007), nuclear magnetic resonance spectroscopy (NMR) (Wuthrich, 1986), and electron microscopy (EM) (Frank, 2006). Each method has both advantages and disadvantages (Table 1). XP and NMR have been used so far mainly to determine structures at atomic resolution. XP has a much higher resolution and limit of molecular weight than NMR, and has been the most utilized method. However, XP first requires preparation of crystals of molecules, which is often difficult. In contrast, NMR does not need crystals, and structures in solution, which are probably closer to their native structures, can be determined. EM is, to date, lower in resolution in comparison to the other methods, but it has a very high molecular weight limit and can be used to determine supramolecular structures. Thus, these methods are often applied collaboratively, and such approaches are called integrative/correlative structure analyses.

X-ray Crystallography

XP has been the most used method to date, and more than 90% of structures in the Protein Data Bank (PDB) were determined by this method (Berman *et al.*, 2000). Biological molecules like proteins in 1–30 mg/mL concentrations produce an aggregate (precipitate) of regularly assembled molecules, that is, crystals, under appropriate solution conditions. A unit cell, which contains defined number of molecules in defined structures, is a virtual building block of crystals (Drenth and Mesters, 2007). The form of a crystal is defined by the axis dimensions (a , b , c), angles between axes (α , β , γ), and symmetry (space groups) of the unit cell. The unit cell is further divided into asymmetric units (ASU), which is the minimum set of atoms that must be determined independently. The unit cell can be reproduced by applying symmetry operations defined by the space group to the ASU, and a whole crystal is constructed by simply compiling unit cells.

Crystals are exposed to an X-ray beam of uniform wavelength and high coherency from a synchrotron or an X-ray generator for diffraction experiments (Fig. 1(a)). An X-ray is light with a wavelength 0.1–100 Å (0.01–10 nm). The electrons in a crystal scatter X-rays, and the scattered X-rays, which have delayed phases depending on the locations of the scatter, interfere with each other.

Table 1 Brief summary of protein structure analysis and validation methods

Method	X-ray crystallography (XP/XRC)	Nuclear magnetic resonance spectroscopy (NMR)	Electron microscopy (EM)
Sample form	Crystal	Solution/powder	Stained/frozen solution on mesh
Probe	X-ray	Microwave	Electron
Direct data	Diffraction intensities	Spectrograms	Particle images
Resolution	<1.0–4.0 Å	~2.5 Å equivalent (to XP)	10–20 Å (2–4 Å in cryo-EM)
Model constraints	Electron density map	Distance/angle constraints	EM density map
Model characteristic (see also Fig. 2)	Atomic model without hydrogens	Multiple atomic models with hydrogens	Subunits fit in map
Specific validation metrics of data	Resolution, completeness, $\langle I/\sigma I \rangle$, R_{sym}	Completeness of signal assignment, number of constraints	Resolution, number of particle images
Specific validation metrics of model	R -factor (R), free R -factor (R_{free})	Average numbers of distance/angle constraint violations, largest distance/angle violations	Map-model cross correlation
Advantage	Atomic resolution	Dynamic structure	Large supramolecule
Disadvantage	Crystallization required (partly fixed in XFEL)	Low MW limit	Low resolution (partly fixed in cryo-EM)

**Fig. 1** Schematic processes of (a) X-ray crystallography, (b) nuclear magnetic resonance spectroscopy, and (c) electron microscopy (cryo-EM).

Therefore, scattered X-rays yield information about the locations of electrons/atoms. Scattered X-rays are very weak and usually cancel each other out. Due to the regular structure of crystals, however, scattered X-rays are not muted in the directions where the phase delay between crystal unit cells is equal to an integer multiple of the wavelength, and such outputs, observed as X-ray spots from the crystal, are called diffractions. Thus, crystals are necessary for XP as “amplifiers” of scattered X-rays.

Resolution is the smallest distance between imaginary mirror planes defined by the unit cell lattice, which diffract (reflect) the incident X-ray, and therefore is the important parameter in judging how finely the structures are measured. The smaller the value, the higher the resolution, and the resolution is typically from 1.0 (very high) to 3.0 Å (low) for protein crystals. Each diffraction spot is indexed with a Miller index (h, k, l), which defines the mirror plane reflecting the corresponding diffraction (mirror plane is defined by three points a/h , b/k , and c/l , where a , b , and c are unit cell axes).

Diffractions are the Fourier transform of electron density in the unit cell. Their intensities are recorded by diffractometers, such as an imaging plate or digital camera. The intensities of diffraction are integrated from the diffraction images. The programs HKL2000 and iMosflm are often used for this process (Battye *et al.*, 2011; Otwinowski and Minor, 1997). The electron density map in a unit cell is retrievable as the inverse Fourier transform of the diffractions. The phase information, however, cannot be recorded by diffractometers, and must be recovered by other means. This is called the phasing problem of XP. Multiple isomorphous replacement (MIR) and anomalous scattering (AS) are experimental methods for recovering phases, in which scatterings from a few heavy atoms introduced into the crystals are overlaid in diffractions in order to deduce phases from the amplitude differences. Molecular replacement (MR) is an alternative computational method, in which calculated phases from homologous protein structures (placed appropriately in the unit cell) are used instead of experimental phases.

Once the electron density is successfully synthesized, an atomic model of the molecule is built so that it fits the density as far as possible, usually half-manually using a computer graphics program (Fig. 2(a)). This process of adjusting the model (set of atomic coordinates) in order to explain diffractions is called refinement, and CCP4, X-PLOR-NIH, SHELEX, and PHENIX program suites are frequently used for this purpose (Adams *et al.*, 2010; Schwieters *et al.*, 2003; Sheldrick, 2008; Winn *et al.*, 2011). The modeling process can be automated if a very fine electron density is obtained.

The small angle X-ray scattering (SAXS) method also utilizes X-rays to determine the overall shape of molecules. When a protein solution (not crystallized) is irradiated with X-rays, the protein molecules scatter X-rays in a spherically averaged manner. The observed X-ray intensity over the scattering angle is converted into the frequency distribution of pairs of points within the molecule, and this pair distance distribution can be used to define the shape of a molecule. Although SAXS does not provide structures in atomic detail, this method is often employed to determine the size, molecular association, and interaction of proteins (Tuukkanen *et al.*, 2017).

Recently, XFEL (X-ray free electron laser) facilities are provided in major synchrotron X-ray sources (Spence, 2017). XFEL is a laser oscillated from accelerated free electrons. Because of its very high intensity and coherency, XFEL can be used for diffraction of microcrystals or even a single particle. Each single microcrystal or particle is exposed to a pulse X-ray of fs (10^{-12} s) duration only once. Therefore, the XFEL diffraction data are theoretically unaffected by X-ray radiation damage, and it enables time-resolved tracing of chemical reactions on 3D structures.

Nuclear Magnetic Resonance Spectroscopy

Atoms behave like magnets (due to the spin magnetic moment of nuclei), and these magnets can be manipulated by radio waves externally. The properties of these atomic magnets depend on the local molecular environment, and their measurement provides information about how the atoms are linked chemically, and how close they are in space. This information can be used to determine the distance between atoms, and then the overall structure of biological molecules (Wuthrich, 2001).

NMR samples are either in solution or solid (typically powder) phases. Usually the protein molecules are labeled with isotopes, such as ^{15}N , ^{13}C , and/or ^2H , to facilitate the measurements. A highly purified protein solution at a concentration of 0.1–3 mM is placed in the superconductance magnet, the sample is irradiated with a series of radio waves (pulse sequence) to activate particular nuclei (spin magnetization), and the radio wave emissions from the sample are measured (Fig. 1(b)).

Fig. 2 Typical model images of (a) X-ray crystallography (atomic models fit into an electron density map), (b) nuclear magnetic resonance spectroscopy (multiple atomic models satisfying distance/angle constraints), and (c) electron microscopy (models fit into a density map).

A series of observed radio wavelengths, expressed as per-million difference (units in ppm) from reference wavelengths are the “fingerprints” of nuclei, and are called chemical shifts. Spin magnetization is transferred through chemical bonds among covalently connected atoms and also through space among atoms in close proximity. The chemical shifts of nuclei are perturbed by the status of adjacent nuclei. Correlation spectrograms, which depict the spin coupling (correlations among nuclei), are measured by magnetizing specific nuclei and observing whether the other nuclei are affected by them. The introduction of multiple isotopes is required to resolve the spectra, which tend to overlap each other (multidimensional NMR spectroscopy).

Various types of multidimensional NMR spectroscopic techniques have been devised to efficiently correct spin coupling, and they are usually combined step by step to construct molecular structural models. Typically, the first step is assigning the chemical shifts to specific residues and atoms using the heteronuclear single-quantum correlation (HSQC) method, in which one amino acid residue (except for proline) gives one signal. The $^1\text{H}^{15}\text{N}$ -HSQC spectra are often referred to as the fingerprint of a protein because each protein has a unique pattern of signal positions. These experiments allow each $^1\text{H}^{15}\text{N}$ peak to be linked to the preceding carbonyl carbon by tracing the coupling between nuclei through chemical bonds with the HNCA (measuring coupling through $\text{C}\alpha\text{--NH--C}\alpha$ atoms of a peptide) and the HN(CO)CA (measuring coupling through $\text{NH--CO--C}\alpha$ atoms of a peptide) methods (Bax and Ikura, 1991). The peaks of sidechain atoms are assigned through COSY (correlation spectroscopy) and TOCSY (total correlation spectroscopy). In this way, chemical shifts are assigned to an amino acid sequence.

Nuclear Overhauser effect (NOE) spectroscopy (NOESY) is additionally required in modeling protein conformation. Because magnetizations are transferred through space in this experiment, NOESY will show cross peaks for all ^1H atoms that are close in space regardless of whether they belong to same residue or not. A cross-peak in a NOESY experiment signifies spatial proximity (~ 6.0 Å) between the two nuclei in question, and thus it is used for distance constraints. NOESY is also used to obtain torsion angle constraints. The experimentally determined constraints of distance and angle are used as input for the structure calculation process. Usually, multiple models, which equally satisfy the constraints, are generated in this process. Computer programs such as XPLOR-NIH, CYANA, or ARIA/CNS attempt to construct atomic models that satisfy as many of the constraints as possible (Fig. 2(b)) (Linge *et al.*, 2001; Schwieters *et al.*, 2017; Wurtz *et al.*, 2017).

Important parameters, such as the interactions and dynamics of molecules, can be additionally obtained with NMR experiments. NMR spectroscopy is nucleus specific; thus, ^1H (hydrogen) and ^2H (deuterium) are distinguished. The amide protons (labeled with ^1H for example) in a peptide exchange readily with the hydrogen of a solvent containing a different isotope ($^2\text{H}_2\text{O}$). This H–D (hydrogen–deuterium) exchange can be used to investigate the folding process of proteins, because the parts of a protein folded early in the folding process are protected from hydrogen–deuterium exchanges (Englander and Kallenbach, 1983).

NOEs are also observed between atoms of a protein and interacting molecules. If the NOE spectrum of a residue is different in the presence and absence of ligands (chemical shift perturbation), it suggests that the residue takes part in the molecular interactions (Meyer and Peters, 2003). NMR can also yield information on the dynamics of a protein by measuring relaxation times, that is, times before magnetizations of nuclei degenerate. NMR relaxation is a consequence of overall or local molecular motions and can be measured by various types of HSQC methods. The motions occur on a time-scale of about 10^{-12} – 10^{-9} s, and usually the relaxation time becomes longer when the molecular motion is faster (Sapienza and Lee, 2010).

Electron Microscopy

EM is a rather intuitive method for determining molecular structures because it directly observes images of the molecule (Adrian *et al.*, 1984; Crowther and Klug, 1975). An electron microscope uses electrons, instead of the light in traditional microscopes, for imaging. High-energy electrons are generated and condensed, and samples are irradiated and focused on detectors by using electromagnets as lenses (Fig. 1(c)). The protein solution samples are adsorbed on a carbon grid and stained by heavy atoms, such as uranium acetate, for contrasting images. In a frequently employed method, the interprotein regions rather than the proteins are stained with heavy atoms, and the method is called negative staining. Recently, a method of rapidly freezing the sample solution in mesh pores, which is called cryo-electron microscopy (cryo-EM), is becoming popular (Cheng *et al.*, 2015). Damage of samples by irradiation and the heavy atom stain is reduced in cryo-EM, although image contrast is generally lower than with the negative staining method.

Transmission electron microscopy (TEM), which observes the electrons transmitted through a sample, is generally used for determining molecular structures. First, images of the biological molecules (particles) spread on a mesh are taken. The images of each particle are generally obscure, and further image processing is required. In the canonical procedure, the particle images are picked up separately, and categorized into clusters of those viewing the same molecule in the same direction. The images in each cluster are aligned and averaged into class averages. The class averages are then assigned Euler angles (of viewing angles), and a 3D molecular density map is constructed with the back-projection method (Orlov *et al.*, 2006).

Usually, back-projection is done in an iterative manner. First, a spherical density map is prepared, and the density map and the assigned Euler angles of the class average are refined step-by-step to be more consistent with each other. Back-projection might be done in either real or reciprocal spaces. The latter method is similar to the synthesis of an electron density map in XP: the 2D class averages are Fourier transformed and assigned angles, and the density map is synthesized as a reverse Fourier transformation. Although these processes might be executed automatically, human intervention is usually required because appropriately selecting particles and/or class averages is often critical for the quality of the final density map. The most used program suites for this process are EMAN2, SPIDER, and Relion (Fernandez-Leiro and Scheres, 2017; Shaikh *et al.*, 2008; Tang *et al.*, 2007).

Molecular structural models are constructed to fit the density map. For standard EM density maps of typical resolution, 10–20 Å, detailed atomic models cannot be constructed based on the maps (Fig. 2(c)). Usually, therefore, the atomic models that have been

determined by XP or NMR are used to build pieces of the model. The pieces (partial models) are placed in the density map so that the experimental and model-derived densities correlate with each other. This process is often executed manually by inspecting the density map on computer graphic programs.

Recently, mainly owing to the development of the direct electron detector (DED), advanced cryogenic technique, and sophisticated image processing software such as Relion, atomic resolution (2–4 Å resolution) analyses have become possible with cryo-EM (Callaway, 2015; Subramaniam *et al.*, 2016). The density map in this resolution range can be interpreted like the electron density maps from XP, and refinement procedures/programs for XP might be used for constructing and refining models (Murshudov, 2016).

Structure Validation Methods

Since protein structures are “theoretical” models that fit experimental data as far as possible, it is very important to detect modeling errors and validate how accurate the constructed models are determined. A structure validation process consists of three major parts: evaluations of (1) experimental data quality/quantity; (2) consistency between experimental data and structural models, that is, to what extent the experimental data is realized in the models; and (3) quality of model atomic coordinates, that is, how much the model parameters deviate from the canonical (dictionary) values derived from certified examples. The former two criteria are mainly specific to each structure-determination method, and only the last one is largely common among all methods (Table 1). The last one is based on a set of rules that any molecules must observe as a real entity, and thus also applicable to evaluation of the models from various computational predictions.

X-ray Crystallography

The quality of XP experimental data can be defined by a large variety of parameters. Among them, resolution, completeness, $\langle I/\sigma I \rangle$, and R_{sym} (also called R_{merg}) are the most fundamental set of parameters (Drenth and Mesters, 2007). Resolution (d) is inversely proportional to the sine of the scattering angle of diffraction (θ) as $2d \sin \theta = n\lambda$ (Bragg's law; λ is X-ray wavelength). Thus, the higher (smaller in figure) the resolution, the larger the number of diffraction data points, and the more finely a structure might be defined. Completeness is the fraction of diffraction data actually observed of that theoretically observable for the resolution range (usually more than 90% is required). The average of diffraction intensity (I) over the standard deviation of the intensity (σI) in the proximal background is $\langle I/\sigma I \rangle$, and the higher the values, the greater the significance of the signals. There are sets of independent diffractions, the intensities of which are theoretically equal due to the nature of diffraction and crystal symmetry. The equivalent diffraction intensities are scaled and averaged into a single datum during the X-ray data reduction process. R_{sym} is the residual of the observed intensities (I) from the averaged one ($\langle I \rangle$) over total intensities, which is defined as $R_{sym} = \sum_{hkl} (I - \langle I \rangle) / \sum_{hkl} \langle I \rangle$. R_{sym} below 0.1 (10%) is preferable.

The consistency of models and experimental data in XP is also evaluated by various criteria, and R -factor and free R -factor are the basic components of such values. R (-factor) represents the residual of observed structure factors (F_o ; square root of I) from those evaluated from the model (F_c), as $R = \sum_{hkl} (|F_o| - |F_c|) / \sum_{hkl} |F_o|$. F_c values are calculated by simulating X-ray diffraction from the model atomic coordinates. R is used as a target function to be minimized during model refinement. Usually, a fraction (5%–10%) of observed diffractions are selected randomly and uniformly over resolution ranges, and are not referenced during refinement for cross-validation purposes. The R -factor calculated on those set-aside diffractions alone is called the free R (R_{free} or fR). Usually, an R below 0.2 (20%) and a difference between R and R_{free} less than 0.1 are acceptable for XP models.

Nuclear Magnetic Resonance Spectroscopy

Due to the difference in methodology, resolution is not definable for NMR data. The quality of data in NMR is defined by the completeness of resonance assignments, that is, to what extent the observed chemical shifts are assigned to specific atoms, and the number of conformational constraints derived from correlation spectroscopy, where a higher number of constraints, if consistent, is preferable (Rosato *et al.*, 2013).

The consistency of models and experimental data in NMR is assessed by the numbers of experimental constraints that were not satisfied by the models, that is, average numbers of distance constraint violations (typically separately evaluated as short 0.1–0.2 Å, middle 0.2–0.5 Å, and long > 0.5 Å ranges, for example) and dihedral angle constraints (also separately evaluated in small 1–10° and large > 10° angle ranges, for example) per structure. The largest distance and dihedral angle violations should also be indicated. Because NMR generates multiple models, these metrics are usually presented as an average and a standard deviation over models. An NOE completeness score, which is defined as the ratio of the number of experimentally observed NOEs to the number of expected NOEs from the model, is also used (Doreleijers *et al.*, 1999).

Electron Microscopy

The major parameters characterizing EM data are the number of particles and map resolution. The number of particles is the number of individual molecular images cut out from the original microscopic images, which often contain hundreds of molecules

in the field of vision. More than 10,000 to 100,000 particle images are usually collected for a structure determination. Because a 3D density map is constructed by back-projection of 2D class averages, a nonbiased distribution of views (Euler angles assigned to class averages) is also required to justify the reconstruction.

Resolution in EM analysis is defined differently from that of XP. To estimate EM map resolution, particle images are randomly divided into two sets of equal numbers, and a map is constructed for each set independently. Then, the density maps are Fourier-transformed, and correlation coefficients (FCS) between sets are evaluated in resolution (wavelength) shells. Generally, the FCS decreases as resolution increases, and the resolution is defined as the point where the FCS falls at 0.5 (low resolution analyses) or 0.143 (high resolution analyses) (Baker *et al.*, 2010).

Consistency of models and experimental data in EM is mainly evaluated as cross correlation between the density of the experimental map and that calculated from the model (Monroe *et al.*, 2017; Xu and Volkman, 2015).

Consistency With Dictionary Values

The stereochemical parameters of model atomic coordinates, such as bond length, bond angle, dihedral angle, and chiral volume, should be statistically consistent with the authentic reference values (Fig. 3(a)) (Evans, 2007). Methods/programs such as PROCHECK or Molprobity are often used for evaluating stereochemical parameters and detecting errors in models (Chen *et al.*, 2010; Hintze *et al.*, 2016; Laskowski *et al.*, 1993). Deposition of structural models in the PDB before publication is recommended/required, and the model atomic coordinates are checked through a program pipeline of the PDB validation server (Gore *et al.*, 2017). The set of scores in the PDB validation report are representative metrics of the stereochemical quality of the models.

The deviations of chemical bond lengths and angles of models from high-quality reference structures (including crystal structures of small molecules) are some of the most fundamental metrics (Bruno *et al.*, 2004). These values are presented as RMSZ, which are the root-mean-square value of the Z-scores (normalized values with average and standard deviation of reference structures) (Tickle, 2007). RMSZ scores of bond length and bond angles are around 0.5 for well-defined models. The root-mean-square deviations in an unnormalized scale are typically ~ 0.01 Å and $\sim 1.2^\circ$ for bond lengths and angles, respectively.

A Ramachandran plot is a traditional yet still-in-use method to characterize the main-chain conformation of proteins (Ramachandran *et al.*, 1963). When main-chain torsion angles ϕ (horizontal axis) are plotted against ψ (vertical axis) (Fig. 3(b)), the plot field is divided into allowed (originally further divided into favored, allowed, and generously allowed regions) and disallowed regions (Fig. 3(c)). Empirically, nearly 100% of residues fall into the allowed region, and the residues outside of this region are thought to be outliers (probable modeling defects). High-quality reference structures contain less than 0.5% of residues as outliers.

The clashscore depicts atomic steric hindrance as the number of too-close contacts per 1000 atoms. An all-atom model is constructed by providing hydrogen atoms on the deposited atomic coordinates, and when van der Waals surfaces overlap more than ~ 0.4 Å between nonbonded atoms, the pair of atoms is identified as a clash (Fig. 3(d)) (Word *et al.*, 1999). An average clashscore in reference structures is 5–20.

Sidechain conformation of amino acid residues can be defined as a set of χ torsion angles. These angles adopt a certain preferred set of values depending on the amino acid. A frequently observed sidechain conformation is called a rotamer or a rotameric conformer. The sidechain conformations observed in less than 0.3% of the residues in reference structures are defined as outliers. Models are scored by the percent of outlier sidechains in total (Williams *et al.*, 2017).

Fig. 3 (a) Schema of basic stereochemical parameters. (b) Definition of main-chain torsion angles ϕ and ψ . (c) Schema of the Ramachandran plot and area participations. (d) An overlap between van der Waals shells of two nonbonded atoms is defined by the lengths of spikes.

Other knowledge-based validation methods are also proposed. For example, a protein structural model with perfect stereochemical parameters may be still “unnatural” because amino acids show preferred distributions in 3D structures depending on their chemical properties, such as hydrophilicity or hydrophobicity. Programs such as PROSA2 or Verify3D are used for evaluating the molecular environments of each residue in a model, and numerically assess the fitness of the residues to the model structure by using an empirically derived function, which is used in threading methods (method to detect fitting of amino acid sequences to protein folds) (Luthy *et al.*, 1992; Wiederstein and Sippl, 2007). These knowledge-based validation methods are often useful to find local mistakes in modeling.

Conclusion and Prospects

Since 1950, when the structure of myoglobin was first determined using XP (Kendrew *et al.*, 1958), many improvements have been made in structure-determination methods, and several revolutionary changes, represented by cryo-EM and XFEL, are currently ongoing. These efforts are largely dedicated to determining large supramolecular structures, and elucidating their functions in atomic detail. Although current validation methods mainly concern the structure of each molecule (subunit), methods suitable to evaluate the correctness of complex structures as a whole will be required in the near future.

Introduction

The usage of graphical presentations greatly helps to successfully describe, communicate or understand structural concepts related to various biological phenomena (Sánchez-Ferrer *et al.*, 1995). A new era of structural biology dawned when the first 3D structure of a protein (myoglobin) was solved by Kendrew *et al.* (1958). They built a physical “ball and spoke” model made of brass at a scale of 5 cm/Å and supported by 2500 vertical rods and colored clips that signified the electron density. The size of the model made it cumbersome and problematic to move whereas the forest of rods obscured the view of the model and made it hard to adjust. Nonetheless, this step was so important that for their studies on the structures of globular proteins, Max Perutz and John C Kendrew won the 1962 Nobel Prize in chemistry. In the meanwhile, Byron Rubin invented a machine for bending wire to follow the backbone trace of a protein and build small backbone wire models. These “wireframe models” were the most manipulable and portable models available at the time. Later during the 1960s and 1970s, the earliest of computer representations for molecules surfaced. Cyrus Levinthal and his colleagues at MIT developed a system that displayed rotating “wireframe” representations of macromolecular structures on an monochrome oscilloscope (Levinthal, 1966). Later, a program known as ORTEP was released by Carroll K. Johnson that could generate stereoscopic drawings of molecular and crystal structures with a pen-plotter. David and Jane Richardson and colleagues (Beem *et al.*, 1977) solved the structure of superoxide dismutase, modeled the metal sites of the enzyme using an interactive density-fitting computer system called “GRIP” and visualized entirely with computers for the first time. Building models for newly solved protein crystals with computers rather than with physical Kendrew-style models became more and more popular.

Since then, scientists all over the world have been studying proteins and other macromolecules at atomic level using structure determination techniques like X-ray, NMR, etc. The availability of protein structures enabled the study of their surfaces and surface characteristics, based on atomic contribution. Consequently, a huge amount of protein structures (134436 on 23 Oct 2017) have been determined and deposited in the Protein Data Bank (PDB; see “Relevant Websites section”) (Berman *et al.*, 2000). PDB stores each structure in a specified format (see “Relevant Websites section”) that describes each molecule as a list of its constituent atoms and their three dimensional (3D) coordinates. This format allows researchers to exchange protein coordinates through a database system. The availability of structural data and advances in computer graphics technologies together have pushed development of computational tools for molecular visualization and analysis (Lesk and Hardman, 1982). Biologists, computer scientists, and application developers usually get together for the development of methods or software for molecular visualization. Some examples of molecular visualization software include VMD (Humphrey *et al.*, 1996), Chimera (Pettersen *et al.*, 2004), and PyMOL (Schrodinger, 2015). In this article, first we describe molecular visualization within the required level of details.

Protein Topology (2D) Visualization

Structural Topology

After determining and analyzing many protein structures, it became clear that protein structures for a particular biological function remained conserved even if the sequences diverged. Wherever 3D structure information is absent, working with secondary structure information can provide a lot of relevant information. In fact, secondary structure information is as important as the final 3D structure of a protein. Therefore, another way of describing the structure of a protein is by describing its 3D fold as a sequence of secondary structure elements (SSEs). These SSEs can be easily assigned using DSSP algorithm (Kabsch and Sander, 1983) and later represented graphically in a diagram. Topology, in terms of protein secondary structure, can be defined as the structural elements which remain unchanged as a protein undergoes continuous deformation, or simply the sequence of SSEs (Martin, 2000). Using these SSEs, several authors have tried to develop a system for the topological classification of proteins (Flower, 1994; Koch *et al.*, 1992; Richardson, 1977). Below we provide the most accepted tools regarding the algorithms and methods used for protein topology depiction and searching/matching.

HERA

HERA is an application for generating hydrogen bonding diagrams for proteins (Hutchinson and Thornton, 1990). The program uses SSEs determined by DSSP algorithm and plots a diagram in which helical residues are represented as helical wheels or helical nets. It also provides an option to automatically search for simple β -sheet motifs in a database. PDBsum (Laskowski *et al.*, 2018), a database which provides summary information about each experimentally determined structure in PDB, uses HERA for generating

hydrogen bonding plots (Laskowski, 2009). An example hydrogen bonding diagram for rabbit L-gulonate 3-dehydrogenase [3ADO] is given in Fig. 1(a).

TOPS

Another such method for plotting protein topology is known as topology cartoons or diagrams (Westhead *et al.*, 1998; Levitt and Chothia, 1976). It has been popular among several others approaches (Richardson, 1977; Tsukamoto *et al.*, 1997; Bansal *et al.*, 2000; Nagano, 1977). The TOPS algorithm was developed to generate topology cartoons for proteins depicting α -helices as circles and β strands with triangles, both of which are used as nodes in a mathematical graph connected by five edge sets (Flores *et al.*, 1994; Westhead *et al.*, 1999). The five edge sets include the directed N- to C-terminal sequential edges, and the four other undirected pairwise relationships between SSEs. The undirected relationships include hydrogen bonding, helix packing, chirality and neighbor relationships. Direction information for strands is duplicated, upward pointing triangles indicating 'up' strands and *vice versa* (Gilbert *et al.*, 1999). It ignores the details like the lengths of SSEs and loops however describes their spatial adjacency within the fold and approximate orientation. One example database that stores this topological descriptions of protein structures is TOPS database (Michalopoulos *et al.*, 2004). TOPS representations and database has been used for visualizing, searching and comparing (especially within a given structural family) fold topologies (Gilbert *et al.*, 2001; Viksna and Gilbert, 2001). Computer scientists and bioinformaticians used it for automated extraction of patterns relating protein sequence to topology and function. Unfortunately, the TOPS servers located at the website provided in "Relevant Websites section" are no more functional. The TOPS graph model was enhanced by replacing the graph model with a new string model (TOPS+) which included previously omitted loops and other structural and biochemical features, like ligand interaction and length of the SSEs (Veeramalai and Gilbert, 2008).

Fig. 1 (a) A hydrogen bonding diagram for rabbit gulonate dehydrogenase [3ADO] using the program HERA. This image has been generated using PDBsum website. (b) Protein topology graph generated for same 3ADO using PTGL. (c) Pro-Origami diagram for 3ADO topology.

Other Approaches for Protein Topology Analysis

Bostick *et al.* developed a topological representation of proteins by identifying natural nearest neighboring residues and the distance between residues in sequence space (Bostick *et al.*, 2004; Bostick and Vaisman, 2003). This representation allowed a quantitative and computationally inexpensive comparison of protein structural topologies. TOPSCAN was developed for a rapid comparison of protein structures (Martin, 2000). It uses a string notation which reduces the protein structure to a topology string where the letters encode the primary or secondary topology. The topology strings describe about 52 vectors of characters and incorporates information (like direction) from the three-dimensional structure. It can be accessed at the website provided in “Relevant Websites section”. On the other hand, Protein Topology Graph Library (PTGL; see “Relevant Websites section”) relies simply on the graph definitions without explicitly considering the order of SSEs (May *et al.*, 2010). Helices and strands are drawn as red circles (or cylinders) and black squares (or arrows), respectively (Fig. 1(b)). It also serves as a database on protein topologies with facilities for search, visualization, and getting additional information. Circuit topology (CT) is the latest method proposed for describing topology in proteins and nucleic acids (Mashaghi *et al.*, 2014). The idea behind CT is that the arrangement of a linear polymer’s intra-molecular contacts (like disulfide bonds) determines its topology. The fundamental rules that intra-chain contacts must obey have been identified and CT can now be used to determine structural equivalence, study the topological structure of genomes and even protein folding. The latest approach for automatically generating protein structure cartoons is Pro-origami (Stivala *et al.*, 2011). Arrows and cylinders are used to depict β -strands and α -helices, respectively, and are drawn proportional in length to the number of residues (Fig. 1(c)). The Pro-origami web server (see “Relevant Websites section”) allows diagrams to be generated from any PDB file.

3D Structure Visualization

Different molecular visualization (MV) software have provided different levels of flexibility to visualize or perform analytical computations. However, one common feature of these programs is that the structural information contained in a PDB file is translated into the position of atoms in 3D space. This positional information when combined with other chemical information like bond connectivity, atom types, atomic radius, electric charges, electron density maps, molecular surfaces, hydrophobicity scales and so on, helps a user observe molecular structure and various other molecular features (Andrei *et al.*, 2012). When not available, the bond connectivity for each atom is usually determined through a nearest-neighbor distance search (Humphrey *et al.*, 1996). Other dimensions of molecular data such as scalar (e.g., charge, hydrophobicity), vector (e.g., force fields, electric field) or tensor (e.g., anisotropic temperature factors) may be spatially located at isolated points in two dimensional (2D) or 3D spaces and may change with time (Duncan *et al.*, 1995). The translation of all this structural data into a geometric representation is a key element of the visualization process. These geometric representations usually are depicted using spheres, lines, polygons, tubes, cones and ellipsoids. Atoms in a molecule are drawn using (solid or dotted) spheres under space-filling (CPK) and variable ball-and-stick representations. These atomic spheres have a radius equal to the van der Waals radius of the depicted atom. Bonds can be drawn either as lines or as cylinders with variable, user selectable radii. Other display attributes such as color, shininess, and opacity can be set independently for each item. The secondary structure elements of a molecule are usually represented using ribbons, licorice, tube, or cartoon representations. Molecular surfaces can also be drawn for the molecules.

Advanced molecular visualization: Besides the basic MV application, most of the MV software can also calculate and represent advanced surface features such as electrostatic potential and hydrophathy using field lines and/or as ranges of colors. The electrostatic potential is usually calculated with algorithms like APBS or DelPhi (Baker *et al.*, 2001; Rocchia *et al.*, 2001) whereas the hydrophathy is calculated using Kyte-Doolittle scale (Kyte and Doolittle, 1982). These basic and advanced components are drawn and displayed as a scene by the MV software. This generated scene can then be output as an image file for storage or publication. The visual quality of a scene can be further enhanced by a technique known as ray-tracing. In ray-tracing, a path is traced from an imaginary eye through each pixel in a virtual screen and the effects of its encounters with virtual objects are simulated. Some examples of algorithms used to ray-trace are POV-Ray and Rayshade. A very high degree of visual realism is achieved using these techniques but at a greater computational cost. The visual experience is further enhanced with additional features like transparency. Transparency is introduced using a variable known as the alpha (α) channel. A concept closely tied to the transparency of an object is the notion that the rendered appearance of that object contributes only partially to the net color assigned to pixels it occludes. Another technique used to enhance the visual appearance of a scene is known as “antialiasing”. The term antialiasing is applied to techniques that reduce the jaggedness of lines and edges in a raster image. Combined together, these algorithms and approaches generate a highly appealing and detailed image of a molecular structure.

Representations

Various ways of representing the constituent atoms of a molecule have been used. Each of them have different advantages and disadvantages. Here we describe some details about the most common representations used by various molecular visualizations software. And, to create a visual distinction between various representations, we depict the structure of insulin, 2HIU (Hua *et al.*, 1995), using VMD (Humphrey *et al.*, 1996) in Fig. 2.

Points: In this representation, each atom is drawn as a point. The bonds are not drawn at all.

Fig. 2 Various molecular representations used to display molecules especially proteins and nucleic acids. Structure of insulin (2HIU) has been used to depict various representations using VMD. Twelve representations have been shown namely (a) lines (b) bonds (c) licorice or Drieden's structure (d) points (e) CPK (f) van der Waals (g) backbone or trace (h) ribbons (i) cartoon (j) dotted (k) solvent and (l) surface.

Lines: In the 'Lines' (or 'wireframe') representation, a line is drawn between each of the bonded atoms. The first half of each bond is colored according to the color of the first atom, while the second half is colored according to the second atom. The user can adjust the line thickness.

Bonds: In this representation, a cylinder is drawn between two atoms instead of a line. This cylinder is drawn as an n -sided prism, where the number of sides and the radius can be specified.

Backbone (or Trace): In this representation, successive residues of unbroken chains are connected by cylinders with adjustable width, in a fashion similar to "Tube". Only the main backbone atoms, $C\alpha$ atoms in case of proteins and $C4'/C3'$ atoms for RNA/DNA, respectively, are considered.

Ball and stick: In this representation, the atoms are displayed as spheres (or balls) whereas the bonds are shown as cylinders (sticks). It is the most fundamental and common representation used where the atoms and bonds are colored according to atom type. The original function of physical ball and stick models were the support of measurements of structure angles and bonds lengths, leaving the real structure representation to space filling models.

VDW: In this representation, the atoms are drawn as spheres with a radius equal to the *van der Waals* radius. The spheres are built using many polygons.

Dotted: This representation is same as VDW except that the spheres are drawn as dotted instead of solid. Like mentioned above, spheres are built using many polygons. Here, a dot is placed at each of the vertices of the triangle making up each sphere. It can be used to speculate about the surface of the molecule.

CPK: This scheme is named after chemists Robert Corey, Linus Pauling and Walter Koltun. This representation draws the atoms as spheres and the bonds as cylinders. The radius of the sphere drawn in CPK mode is usually smaller than VDW mode. Therefore, it can be called as a combination of both *Bonds* and VDW. It is also called as the space filling model.

Licorice or Dreiding model: In this representation, the atoms and bonds are drawn as spheres and cylinders, respectively. The sphere radius is not controllable and is same size as the bond. Therefore, it contains less distractors compared to the normal ball-and-stick.

Tube: The tube representation is a smooth spline curve that passes through backbone atom of proteins ($C\alpha$) or nucleic acids (P atoms of phosphates). The spline radius and resolution can be set by the user. The curve connecting the two $C\alpha$ atoms is broken into six line segments by determining five evenly spaced interpolation points along the spline curve. The first three segments are colored by the color assigned to first $C\alpha$ and the last three segments are colored by the color of the second $C\alpha$.

Ribbon: This representation also follows the same spline curve for both the protein and nucleic acids as in Tube. Additionally, it uses the O atom of the protein backbone or some of the phosphate oxygens for nucleic acids to find a normal for drawing the oriented ribbon. Given the coordinates of each atom and the offset vector for the ribbon vector, the drawing code finds the spline curves for the top and bottom of the ribbon. The two splines are connected by triangles and both splines are drawn as small tubes.

Cartoon: This representation is based on the secondary structure of the protein. Helices are drawn as cylinders, beta sheets as solid ribbons, and all other structures (coils and turns) as a tube. A least squares linear fit along at least three $C\alpha$ atoms of the helix is used to construct a helix cylinder. The solid beta ribbon is constructed by building a spline along the center points between each beta sheet residue.

Solvent: This representation gives a quick estimate of the molecular surface with a collection of dots. It is similar to the *Dotted* representation and provides a more uniform coverage of the surface. The "probe radius" and "density of the dots" can be set or adjusted by the user.

Surface: This representation uses a molecular surface renderer for example MSMS which allows to compute very efficiently triangulations of solvent excluded surfaces. Representation of molecular surfaces needs a special detailed description. Therefore, below we have provided some details on the rendering of molecular surfaces.

Molecular Surface

Molecular surface (MS) is one of the most important geometric feature of a protein as the size and shape of indentations in the surface play an important role in various functions like protein folding, docking and interactions between proteins (Connolly, 1983). The computation of MS area is important for the understanding of interactions of protein surfaces and internal cavities with ligands and hence crucial in structure-based drug design. It also allows one to incorporate the effects of solvent in the potential energy calculations (Juba and Varshney, 2008). Molecular surfaces are most usually displayed as dot-surfaces or solid renderings. Various algorithms have been developed for molecular surface area computation for example Connolly's (Connolly, 1983), MSMS (Sanner *et al.*, 1996), GETAREA (Lesk and Hardman, 1982), LSMS (Humphrey *et al.*, 1996), 3V (Pettersen *et al.*, 2004), and an adaptive grid-based algorithm (Schrodinger, 2015) included in TexMol (Kabsch and Sander, 1983). Some software that have been used for surface depiction include Grasp, AVS, VOIDOO, etc.

Broadly, three types of molecular surface models have been described which are van der Waals (vdW) surface, solvent-accessible-surface (SAS), and solvent excluded surface (SES) (Deanda and Pearlman, 2002). Ligand excluded surface is an extension of the SES concept. Below these surfaces have been described.

Van der Waals surface: This surface is a reasonable approximation of the molecular surface. Here the atomic radius of each atom is its van der Waals radius and each atom is represented as a hard sphere. Therefore, the van der Waals surface of the molecule can be defined as the union of all portions of all atomic sphere surfaces not occluded by neighboring atomic spheres.

Solvent accessible surface (SAS): Atoms located in narrow crevices may not be accessible to the solvent if the solvent molecule is bigger than the crevice. Therefore, SAS is calculated by rolling a probe sphere of a defined radius (e.g., 1.50 Å for a water molecule)

over the entire van der Waals surface of a molecule of interest. The molecular surface created by the center of the probe is called as SAS (Lee and Richards, 1971).

Solvent excluded surface (SES): SES is also calculated by rolling a probe sphere of a defined radius over the entire van der Waals surface of a molecule. However unlike SAS, SES is defined as the surface traced out by the inward-facing (towards the macro-molecule) surface of a probe sphere (Richards, 1977; Greer and Bush, 1978). In other words, SES resembles the van der Waals surface of the molecule except that crevices too small for the probe sphere to enter are eliminated whereas the clefts between atoms are smoothed over. SES area provides a better model for describing hydration effects and a better choice to visualize and study molecular properties. Surface computation is easier for the vdW and SAS but not for the SES.

Ligand excluded surface (LES): LES represents a more accurate approximation of the regions accessible to the ligand under consideration than SES because here the probe sphere is replaced with the full vdWs geometry of the ligand.

Other advanced approaches for surface representation: Voronoi diagram of atoms, is an approach that is independent of the probe size therefore invariable for a given molecule, have also been used to calculate MS of a molecule (Ryu *et al.*, 2007). With advancements in GPU hardware, several alternative approaches have been proposed for faster rendering of molecular surfaces like ambient occlusion, halos, GPU ray-casting, improved ball-and-stick representation called “HyperBalls”, theory of implicit surfaces, depth peeling, tessellation shaders, and dynamic view-dependent level-of-detail (LOD) representation have been proposed (Guo *et al.*, 2015).

Ray Tracing

Shaded images for displaying molecules have been a popular approach for conveying 3D information especially in the absence of animation. Therefore, algorithms have been developed that can handle reflections, transparency with refraction, shadows, intensity depth cuing, texturing and multiple local light sources. Ray-tracing algorithms provide the best solution to these aspects and are capable of generating realistic visual effects that are difficult with other rendering techniques (Palmer *et al.*, 1989). During ray tracing, a ray is fired from the eye point through each pixel in the image where it can either get reflected or transmitted through the surface (refraction). This reflected or transmitted ray can further interact with other surfaces, until it gets terminated after either leaving the scene or being absorbed. Ray tracing is capable of simulating motion blur, soft shadows, depth of field, diffuse inter-reflections and caustics by using various extensions.

Ray tracing in a scene requires a substantial additional computational cost compared to a non-ray-traced scene which is a significant problem. Nonetheless, ray tracing amplifies the clarity of a structure enormously. Fig. 3 compares a non-ray-traced image of insulin (2HIU (Hua *et al.*, 1995)) with a ray-traced version using the *spheres* (van der Waals) representation using PyMOL (Brunger and Wells, 2009). Ray tracing is an effective and flexible technique for producing high-quality visualizations of molecular structures especially for scientific publications. Persistence-of-vision (POV) ray (see “Relevant Websites section”), RADIANCE (see “Relevant Websites section”) and OSPRay (see “Relevant Websites section”) are some of the many ray tracing software available online.

Depth Perception

Depth perception in 2D is conveyed by motion cues during rotation and (directional) lighting. Surfaces where light bounces off the surface and is reflected toward the viewer appear bright and give a strong sense of depth for smooth, slowly varying surfaces. Lighting

Fig. 3 The advantage of ray tracing in amplifying the clarity of a structure has been depicted using (a) non ray-traced and (b) ray-traced images of insulin (2HIU) in *spheres* (van der Waals) representation using PyMOL.

techniques like ambient occlusion are computationally demanding but appear highly effective for such space-filling sphere rendering as surface regions in recesses or concavities appear darker. Fig. 4 depicts how PyMol overlays fog on objects to assist in emphasizing what is in the foreground and background of the image with respect to the camera. Another technique to enhance 3D appearance to highlight protrusions of a surface overlaying an identically colored surface is to add black outlines at edges where a jump in depth occurs in an image. An improvement to this algorithm was introduced to make the line thickness depend on the magnitude of the depth change so that larger depth changes are highlighted with thicker lines while small depth jumps may not be highlighted to simplify appearance (Goddard and Ferrin, 2007). Similarly, eliminating depth is another alternative approach that is getting attention. For larger assemblies, the individual residues appear like countries on a map divided by boundary lines with text labels. Recent graphics processing units (GPUs) frequently have an order of magnitude more floating-point computation speed than the main “computer processing unit”. Some GPU-based techniques called textural and procedural impostors enable rendering of atomic models faster by a factor of 10 or more. Therefore, new effects such as the depth-dependent edge highlighting are possible.

Visualizing Molecular Dynamics Trajectories

Molecular dynamics (MD) studies of the function of the structurally known biopolymers are being widely applied. The results of such studies are typically large molecular trajectory files consisting of hundreds or thousands of frames of atomic coordinates. The trajectories contain substantial amounts of dynamical data that require suitable visualization tools to display sequences of structures (Humphrey *et al.*, 1996). Therefore, programs were developed that could display the molecular structure in motion. The investigator may relate various thermodynamic quantities better to molecular motions by the complementarity provided by molecular visualization. Indeed, by visualizing a computational model it becomes easier to have a subjective assessment or make a non-quantitative judgment.

Visualization of Molecular Assemblies

The hierarchy of organization of atoms in a biomolecule may start from atoms and go to secondary, tertiary and quaternary structures. For certain systems this hierarchy may even be followed by further organization into molecular complexes such as virus

Fig. 4 The perception of depth in a scene is depicted using the structure of EFG receptor (2JIT) in the *cartoon* representation using PyMOL. (a) Without depth cueing and (b) with depth cueing. The obscurity and haziness of the distant domain of EGFR clearly depicts the impact of depth cueing.

capsids. The visualization software would be required to render millions to billions of atoms in real time. Therefore, visualization of larger biological structures needs a humongous computational power and is still a challenging task. To circumvent this problem, lesser details for each component of the larger assemblies are used to decrease the computational burden (Goddard and Ferrin, 2007). The approximate shape of domains, molecules, or complexes are drawn as smooth surfaces at any desired resolution using methods like spherical harmonics, density contours, and surface decimation. Each method has its own advantage and disadvantage but discussing that is beyond the scope of this article.

Evolution of Molecular Visualization Software

A number of molecular visualization programs have been developed since the days of first molecular visualization using computers. These programs use component modules each specifically written to create the structural components like spheres, tubes, ribbons, etc. Not all the programs can be described in this article but we try to describe the best known molecular visualization programs. The programs are arranged according to their year of release to generate a sense of evolution in terms of molecular visualization. Each program is listed and the capabilities and mode of action of the underlying algorithm(s) have been described.

RIBBONS (1987)

Mike Carson constructed an algorithm that generated aesthetically pleasing and smooth 3D representations of a protein using a set of nearly parallel B-spline curves fitted to the peptide plane (Carson, 1987). The peptide planes were used to generate a series of 'guide coordinates' equally spaced along the desired ribbon width. Smooth and regular cubic B-spline curves fitted to these guide coordinates formed the roughly parallel threads of the ribbon. Ribbon models clearly displayed the secondary structure of the backbone. It was also possible to code by residue to depict information such as residue type or temperature factors.

MAGE (1992)

A "kinemage" or kinetic image was a term designed for a structure presented on a computer display (Richardson and Richardson, 1992). A utility called PREKIN was used to prepare kinemage files from input PDB files which were then viewed using a graphics program called MAGE. The kinemages were plain text files with commented display lists and accompanying explanations that could be edited by user. The interactive image could be rotated in real time, parts of the display could be turned on or off, cursor selection of atoms or points was possible, and different forms could be changed. The depth-cueing, rotation, rocking, distance measurement and animation of two or more conformations was possible.

RasMol (1993)

RasMol (stands for *raster molecules*) is an easy to use molecular visualization tool for proteins, nucleic acids and small molecules (Sayle and Milner-White, 1995). It was developed by Roger A. Sayle (*also forms R.A.S. of RasMol*) for Unix, Windows and Macintoshes and is available freely from the websites provided in "Relevant Websites section". Rasmol can read a PDB file both locally or directly from PDB database, which can then be displayed interactively with a variety of color schemes and molecule representations including depth-cued wireframes, 'Dreiding' sticks, spacefilling (CPK) spheres, ball and stick, solid and strand biomolecular ribbons, hydrogen bonding and dot surfaces (Sayle and Milner-White, 1995). The users could interact with a molecule by rotating, translating, zooming and z-clipping (slabbed) using either the mouse, scroll bars, command line or an attached dial box. Ligands, active sites, multiple subunits, hydrogen bonds and various parts of the molecule could be displayed selectively or in a combination of display modes. It could measure interactive distances, angles and torsion angles. RasMol allowed depiction of stereo images, multiple NMR models and labeling of atoms. The structural features like β -sheets, protein backbones, double and triple bonds were represented as arrows, smoothed-tube, multiple lines and, respectively. RasMol can also take a list of commands using a 'script' file to (re)generate a given image or viewpoint that may be written out in a variety of formats, e.g., PostScript, GIF, BMP, etc. No doubt, RasMol quickly became the most popular molecular graphics software with over 15,000 sites using it.

AVS (1995)

AVS or Advanced Visual Systems, was designed to be a general-purpose visualization environment with no elaborate data structures for specific applications areas (Duncan *et al.*, 1995). Several programs, e.g., AutoDock, Harmony and SURFDock use AVS as an important visualization tool as the rendering capability of AVS is of very high quality. AVS uses several modules to translate molecular coordinate data to a geometric representation, e.g., SPHERES (for spheres), DISJLINES (for bonds), POLYLINE, POLYGON (to define triangles, and other convex polygons), POLYTUBE (a cylindrical object from a polyline), ELBOW (for smooth joints), COLORTUBE (produces a tube from disjoint line), MSMS (for molecular surfaces), MV102 (to control the display style of selected subset of atoms). Intermolecular interfaces can be calculated using the INTERFACE module. The PLAY BINPOS

module displays MD simulation trajectories with facilities for selecting individual frames and controlling the speed of the display. Both, a graphical user interface (GUI) and a command line interpreter (CLI) can be used to control most interactions with AVS. AVStk, a Tcl/Tk interface to AVS implements the facilities for expressions, variable assignment, loop control, or functions. The NAB (nucleic acid builder) language is used for building chemistry modules as it has data structures and operations designed specifically for molecular data. AVS is suitable for biomolecular visualization as it provided general-purpose and chemistry-specific modules, and AVS-tool and NAB to facilitate network control and module development.

Raster3D (1996)

Raster3D is a hardware independent suite of programs used to generate photorealistic molecular graphics (Merritt and Bacon, 1997). It is available for various Windows, various linux distributions and macintosh operating systems. It offered several advantages compared to other available programs. For example, it provided platform-independent tools for composition and rendering. It was much faster than general-purpose ray-tracing programs. Raster3D suite has four different types of programs namely, composition tools (*balls*, *ribbon*, and *rods*), input conversion utilities, the central rendering program, and output conversion filters. The composition tools read the atomic coordinates found in a PDB formatted file and generate van der Waals surface (*balls*), a peptide backbone trace (*ribbons*) and a ball-and-stick model (*rods*) of the bonded atoms. This information is stored or converted into a series of header lines specifying global rendering options, followed by a series of individual object descriptors. The input stream can have further input from one or more files. Also, the size of the rendered image in pixels could be controlled using header records input to the render program. The main program of the Raster3D suite, *render*, takes this input and produces a raster image in one of three standard formats (AVS, TIFF, or SGI libimage). Rendered images could be processed further to add labels, edit colors, form composite images, apply “gamma correction” or be converted to other formats. Raster3D could also import objects from other molecular visualization tools using two conversion utilities *ungrasp* and *normal3d*.

Raster3D generated *shadows* to convey an impression of depth, obviate the need for stereo pairs and to convey information that otherwise would not be apparent in the rendered image (Merritt and Bacon, 1997). Raster3D implemented “Z buffer” algorithms rather than true ray tracing to produce a remarkably photorealistic appearance for the rendered objects. The rendering algorithm can be optimized to output images that include effects like shading, transparency and effective transparency (or α channel). It required much less computation than full ray tracing of the same scene. One can generate various kinds of pictures in Raster3d such as black and white, colored, and animated images. We can also add labels, shadows, transparency and stereo images. Ribbons, ring, surface and rods are the common kinds of representations available. It has been implemented in other protein visualization packages such as VMD, Xtalview, Molscript, GRASP, MSMS, ORTEX, Conscript, etc.

MD Display (1996)

MD Display was developed initially as a means of visualizing molecular dynamic trajectories generated by Amber (Callahan et al., 1996). The program runs on Silicon Graphics workstations, and features a simple user interface, and convenient display and analysis options. The program can accept input from several other molecular dynamics programs. A preprocessor handles output files from different computational programs (like Amber, CHARMM, Discover, and GROMOS) and to generate a consistent input for the display program. It can load PDB files and allows construction of a pseudo-trajectory using multiple PDB files. It provides animation control in terms of speed (and *hyperspeed*) and direction of animation so that freezing one frame and single step in either direction is possible in the frame sequence. Periodic boundary conditions are handled and multiple frames can also be superimposed to create a “smear” image. The user can monitor the interatomic distances, angles, dihedrals, hydrogen bonds (based on donor-acceptor distances), and Ramachandran plot (ϕ - ψ values) in the trajectory.

MOLMOL (1996)

MOLMOL is developed specifically for the display, analysis, and manipulation of sets of conformers in nuclear magnetic resonance (NMR) structures of proteins and nucleic acids (Koradi et al., 1996). It is downloadable from the website provided in “Relevant Websites section”. It also implemented special functions to represent the structural uncertainty by the spatial spread among groups of NMR conformers. It could be run on Silicon Graphics workstations, unix machines using either OpenGL or X11 library. The selection of sets of atoms, bonds, distances, or primitives was possible by expression syntax or mouse. This selected set could be represented as ribbons, ellipsoids, or other simple geometric shapes. The secondary structures were either identified using the DSSP algorithm or read directly from the PDB file. MOLMOL can draw dots or shaded molecular surfaces for three different kinds of surfaces namely van der Waals surfaces, solvent accessible surfaces and contact (SES) surfaces.

This program was unique as it allowed modification of chemical structures by adding and deleting atoms and bonds, and generation of new 3D structures by variation of dihedral angles about individual covalent bonds. It could also analyze the trajectories from MD simulations. For quantitative comparisons, the program calculated root mean square distances (RMSDs), short interatomic contacts, dihedral angles, hydrogen bonds, radius of gyration and solvent-accessible surfaces. The program could generate high-quality plots as PostScript, or FrameMaker (MIF), TIFF format or as an input file for ray-tracing programs.

Cn3D (1996)

Cn3D (pronounced ‘see in threedee’) is a visualization tool developed by NCBI to simultaneously display biomolecular structures, sequences, and sequence alignments for all platforms (Hogue, 1997; Wang *et al.*, 2000). It provided all the functionality of RASMOL along with other enhanced rendering and labeling options. It could also play animations for multiple conformations of NMR structures or multiple superposed structures. To provide a better understanding of the 3D structure, by default the protein’s α -carbon trace is colored by secondary structure and α -helices are rendered as hollow cylinders whereas a DNA molecule is colored by CPK color scheme and metal ions are shown as spheres. It is also possible to ‘hide’ chains, domains or residues at one’s discretion. It is also easy to set custom rendering or labeling for a set of atoms or residues. It offers a programming layer as MMDB-API along with a GUI called Viewer3D. The co-ordinates data from a PDB file is translated into MMDB-API representation and converted to graphics primitives (like spheres, cylinders, lines, etc.) to be displayed in Viewer3D.

Cn3D includes algorithms to import and align multiple sequences or structures. Homologous sequences to a protein with known 3D structure can be imported and aligned into the sequence viewer. After importing multiple homologous sequences, the structure window displays the 3D superposition while the sequence window shows a sequence view of the structural alignment. A seamless combination of structure visualization and comparative analysis makes Cn3D a powerful tool to map functional sites between structure and sequence. This proves helpful in finding conserved regions among aligned proteins, locating the residues corresponding to known disease mutations in a crystal structure or mapping the locations of conserved binding site or active site residues from a family of homologous sequences. Because of these capabilities, Cn3D is the default structure viewer for NCBI’s Entrez Structure database and the primary alignment curation tool for the CDD project (Wang *et al.*, 2000). Cn3D also has powerful annotation and alignment editing features.

VMD (1996)

VMD, stands for Visual Molecular Dynamics, is a tool written in C++ and designed to visualize structural features of various biopolymers like proteins and nucleic acids using a wide variety of rendering styles and coloring methods (Humphrey *et al.*, 1996). The source code and documentation for VMD is available at the website provided in “Relevant Websites section”. VMD can display standard PDB files and animate trajectories obtained from molecular dynamics (MD) simulations. The trajectories can be loaded both from stored files and from a direct connection to a MD simulation running on a remote supercomputer or high-performance workstation. For remote trajectory sources, VMD uses a set of daemons and library routines known as the MDCOMM that buffer data transfer from the remote connection. A portable MD simulation program called NAMD, available with VMD, has been designed for performance, scalability and modularity to take advantage of the parallel architecture of processors. VMD together with NAMD constituted a larger set of computational tools for structural biology known as MDScope (Nelson *et al.*, 1995).

VMD requires Silicon Graphics GL library or the OpenGL library for 3D graphics rendering. The GUI can be used to perform tasks such as changing the current molecular display characteristics or animating selected molecules using molecular dynamics trajectories. All actions in VMD are available *via* text commands so that users can write and execute their own *tcl* scripts. To read data from file formats other than PDB, VMD has an interface to Babel (Walters and Stahl, 1996) to read data from other formats. Molecules are drawn as one or more “representations” for all or a subset of constituent atoms. A particular set of atoms can be selected using Boolean operators and regular expressions and assigned one of the various rendering styles and coloring schemes. The solid objects are illuminated using up to four hardware-accelerated, independent, infinitely distant light sources. VMD provides an extensive program control, using both graphical user interface (GUI) and a text interface using the *Tcl* embeddable parser, to generate high-resolution raster images for photorealistic image-rendering applications.

Trajectory display and analysis: As the name suggests, VMD was primarily developed with the ability to animate and study molecular dynamics (MD) simulations. A molecular trajectory may be read (from PDB files or from direct connection) and edited (using a trajectory editor) that provides options to delete or write (*to a new file*) specific frames or set of frames. VMD can also perform complex analysis on a molecular dynamics trajectory such as computing the RMS deviation or correlation functions. With the advent of petascale computers (e.g., Blue Waters supercomputer) and GPU-accelerated ray tracing engine, atomic-detail simulation and visualization of really large cellular apparatus and processes like the 100 M-atom photosynthetic membrane complex in purple bacteria, is feasible with VMD (Stone *et al.*, 2016).

WebMol (1997)

With the advent of Java and web-browsers with in-built support for Java applications, programs could be run virtually and remotely using regular web-browsers. The client computer system doesn’t need to install the programs code (‘program once - run anywhere’) because Java programs are directly transferred and interpreted to the client upon request. One such application for molecular visualization, called WebMol, was developed at EMBL.

WebMol is a Java based interactive graphical program to display and analyze molecular structures stored locally or remotely in the PDB database using Java-supporting web-browsers only (Walther, 1997). It provided a similar functionality online as RasMol provided offline but suffered slow rendering and java-dependent security problems. The main advantage was that novice users didn’t require to install programs or their source codes. They could directly go to WebMol and start visualizing or analyzing molecular structures. A new version of WebMol (see “Relevant Websites section”) is under development in HTML5 and Javascript

with the support of PhiloGL. The application is designed to be accessible from Internet and compatible with the JSON format of protein provided by the project WebPdb (see “Relevant Websites section”).

PyMOL (1999)

PyMOL is an elegant open source and cross-platform program for visualization of complex macromolecular systems based on OpenGL and Python (Schrodinger, 2015). PyMOL can be downloaded freely for common platforms like Windows, Linux, and Mac OSX from the website provided in “Relevant Websites section” (v1.8) or from the website provided in “Relevant Websites section” (v2.0). Along with a graphical user interface (GUI), PyMOL offers a command line mode that resembles the Python interpreter. In fact, ‘Py’ part in PyMOL refers to the programming language Python. PyMOL commands are a series of Python function calls that function as a superset of the Python language. It also supports reusable scripts written in the PyMOL command language or in Python. PyMOL supports most of the common representations like wire, cylinders, backbone and cartoon ribbons, spheres, ball-and-stick, dot surfaces, solid surfaces, wire mesh surfaces. It supports labels, dashed bonds (for hydrogen bonding interactions and distances), transparent surfaces, reads and displays CCP4 and XPLOR electron density map files, generate symmetry-related molecules and load multiple common file formats. PyMOL was the first intuitive molecular graphics program that provided the click-and-drag functionality that we now see in almost all the molecular visualization software, no doubt it became really popular (Brunger and Wells, 2009). PyMOL was originally designed to dynamically visualize single or multiple conformations (trajectories or conformational ensembles) of a single structure with professional strength graphics. It has an integrated ray-tracing engine (in addition to PovRay engine) for generating publication quality figures that are complete with lighting, specular reflections, and shadows. Fig. 5 depicts some of the representations available in PyMOL for the same insulin structure (2HIU (Hua *et al.*, 1995)). Indeed, figures generated with PyMol appear superior than many other software. This obviated the need for command-line operations which were otherwise required by other programs such as Molscript, Raster3D, and ImageMagick. Different states of molecule can be assembled into QuickTime or AVI movie by rendering simple or Ray-traced frames. Multiple atom selection was made possible using arbitrary extended algebraic expressions. Molecular editing allowed users to create new objects out of atom selections (across any number of other objects) and edit (delete, replace, or grow) bonds, angles, torsions, and positions on an atomic basis using just click-and-drag operation. Another important aspect of PyMOL is that other applications can utilize it as a molecular display window while providing their own external menus, windows, dialog boxes, and controls or even add additional geometries. PyMOL can also display the results of the macromolecular electrostatics calculations by APBS (Baker *et al.*, 2001) as an electrostatic potential molecular surface using the APBS Plugin. PyMOL also provides an automated qualitative electrostatic representation for a protein’s contact potential by generating a charge-smoothed surface. It performs a “charge smoothing” using a quasi-Coulombic-shaped convolution function to average the charges over a small region of space. Fig. 6 displays such an electrostatic contact potential for insulin generated using PyMOL.

UCSF Chimera (2004)

The developments in electron microscopy (EM) led to the determination of the atomic resolution structure of large-scale sub-cellular systems. Compared to other crystallographic and NMR structures, which are usually not very large, the structural complexity for large-scale molecular assemblies like viral particles, chaperonins and chromosomes, increases rapidly. Such large assemblies or molecules may contain several million atoms and therefore normal visualization software may not be able display it properly. The reason is that normal representations are so detailed that it requires impractically large computer memory and leads to insufficient graphics rendering speed (Goddard *et al.*, 2005). Therefore, to display such large molecules, better algorithms are required that can perform higher order calculations efficiently on desktop computing resources. UCSF Chimera was launched as a solution to this problem (Goddard *et al.*, 2007). Chimera is Python based freely available to academic and nonprofit users from the website provided in “Relevant Websites section”. Its GUI and command-line interfaces provide rich and overlapping sets of functionality under Windows, Mac OSX and Linux or other unix based systems. It generates a mixture of low-resolution depictions of assembly components with high resolution depiction of regions of interest to avoid the above-mentioned drawbacks. It offers interactive visualization and analysis of atomic-resolution molecular models as well as specialized capabilities for low resolution depictions, contact calculations and quaternary structure navigation to study large multimeric assemblies such as virus capsids, ribosomes, microtubules, etc. To interactively explore such large complexes, it is important to have the abilities to build multimeric forms, display low-resolution representations and define levels of structure. The widely used molecular visualization programs can also display such density maps but do not offer a broad selection of tools for studying macromolecules.

Chimera was designed from its predecessor MIDAS (Ferrin *et al.*, 1988) with extensibility as a primary goal. Therefore, the architecture of Chimera is composed of a core, for basic services and state-of-the-art visualization, and extensions that provide all extra higher level functionality (Pettersen *et al.*, 2004). The C++ based functions in “core” can perform molecular file input/output, graphical display as representations (e.g., wire-frame, ball-and-stick, ribbon, and sphere), generation of molecular surface using MSMS algorithm, select parts of structures, control transparency, near and far clipping planes, and lenses. On the other hand, the extensions include *Multiscale*, to visualize large-scale molecular assemblies; *Collaboratory*, to share Chimera sessions remotely in real time; *Multalign Viewer*, for reading, writing and displaying multiple sequence alignments together with associated structures; *ViewDock*, facilitates interactive screening of docked ligand orientations from DOCK; *Movie*, for displaying and saving MD

Fig. 5 Molecular representations used in PyMOL to display proteins and other types molecules. Structure of insulin (2HIU) for all these representations namely (a) lines (b) sticks (c) ball and stick (d) ribbons (e) cartoon (f) dots (g) mesh (h) spheres (i) and (j) surface.

trajectories as a video; and *Volume Viewer*, for displaying volumetric data as isosurfaces, meshes, and translucent solids. It now also integrates MODELLER and other modeling tools for structural modeling of multiprotein complexes from sequence to 3D structure (Yang *et al.*, 2012). High-quality images and animations can be generated for publication using Chimera.

Jmol (2004)

Jmol has been developed as an open source Java-based molecular visualization software by an active user community of professional crystallographers, educators and students over many years (Herraez, 2006). Initially, it was made available at the website provided in “Relevant Websites section” however currently, it is available from the website provided in “Relevant Websites section”. Jmol creates every pixel of the model on the fly, using exceptionally efficient rastering techniques and without any external 3D graphics packages. That is why Jmol runs independent of the operating system (like Linux, Windows or Macintosh OS) and the browsers. It was designed as a web-based replacement for RasMol or Chime (Rasmol as a web browser plug-in) for crystallographic visualization and analysis. Being web-based, Jmol offered possibilities of revolutionizing the way we learned

Fig. 6 A qualitative representation for insulin's (2HIU) electrostatic contact potential generated by PyMOL using a charge-smoothed surface. The "charge smoothing" is performed by averaging the charges over a small region of space.

about molecular structure (Hanson, 2010; Cass *et al.*, 2005). Jmol can read, display, manipulate, analyze, and output data from molecular structures stored in various file formats. It allowed diverse molecular representations like wireframe, sticks, balls and sticks, spheres, ribbons and cartoons. Its extensive mathematical scripting capability allows extensive analysis of molecular structure by writing functions/scripts using the popular command flow syntaxes. It can produce high-quality images in popular formats like JPG and PNG with or without point-of-view ray (POV-Ray) tracing. Jmol can also depict electron density maps and isotropic B-value ('temperature') data. Finally, it can also be used to read, load and display MD simulations trajectories.

Bioblender (2012)

Traditionally, the electrostatic and hydrophobic characteristics of proteins are visualized as range of colors that vary according to the tool used. The simultaneous visualization of both these properties has been almost impossible, except when visualized in different images. A novel and intuitive software, BioBlender, attempts to describe protein motion with simultaneous visualization of their chemical and physical features (Andrei *et al.*, 2012). It can be downloaded freely from the website provided in "Relevant Websites section" for Windows, Linux and Macintosh. It has been developed as an add-on to an open-source, free, and cross-platform application called as Blender that can access several scientific programs. BioBlender uses Python based scripts for building the interface, various calculations and managing other component programs like PyMOL (for loading PDB files, molecular surface calculations), PDB2PQR (for continuum electrostatics calculations), APBS (for calculating the electrostatic potential), and Blender (for 3D graphics). Blender itself has many benefits, one of them is that physics-based animations can be achieved by simulating forces such as gravity, magnetic, vortex, wind, etc.

BioBlender has introduced simultaneous representation of surface physico-chemical properties of proteins, even in motion. Using features different from color permits their simultaneous delivery in photo-realistic images leaving the utilization of color space for the description of other biochemical information. The new visual code introduced in BioBlender entails the depiction of molecular lipophilic potential (MLP) as a range of optical features going from smooth-shiny for hydrophobic regions to rough-dull for hydrophilic ones. Similarly, animated line particles are used for electrostatic potential (EP) that flow along field lines, proportional to the total charge of the protein (Andrei *et al.*, 2012). A python script named "*pyMLP.py*" is used to calculate the MLP for the protein space. Finally, a custom software "*scivis.exe*" is used to calculate field lines. Therefore, the outcome is the ability to visualize the molecular surface, the EP grid, the gradient grid and the field lines. A continuous perception and visualization of molecular features can be generated by the program using various conformations of macromolecules during their motion. For a protein in motion or with multiple conformations, BioBlender uses Blender Game Engine (BGE). BGE is equipped with special rules to simulate atomic behavior, to interpolate between known conformations and obtain a physically plausible sequence of intermediate conformations. The program gives as output both the intermediate PDB files and the rendered images as a movie. This approach makes nanoscale "un-seen" phenomena such as hydrophathy or charges of proteins become more understandable and familiar to our everyday life by drawing viewer's attention to the most active regions of the protein.

JSmol (2013)

JSmol is a JavaScript-only version of Jmol (Hanson, 2010) with the complete set of Jmol functionalities (Hanson *et al.*, 2013). Being Java-based has its own demerits in terms of security. Therefore, Java does not run on some handheld devices but JavaScript

(JS) does. Therefore, Jmol has been completely rewritten in JavaScript to produce identical graphical results. Thus, JSmol is the first full-featured molecular viewer based on JS, and the first ever JS-based viewer for proteins. For small molecules it performs at par with Jmol, but for larger molecules it doesn't scale as Jmol. Nonetheless, JSmol has been successfully implemented in Proteopedia (Hanson *et al.*, 2013; Prilusky *et al.*, 2011).

YASARA View (2015)

The spherical representation of an atom usually requires about 320 triangles, therefore visualizing larger proteins with atomic details requires tens of millions of triangles, far too many for smooth interactive frame rates. A new algorithm called YASARA View was designed to solve this problem (Krieger and Friend, 2014). It does not depend on high-end shader tricks and therefore works on smartphones too. Too complex objects are replaced with 'impostors', i.e., entities that have pre-calculated textures attached, which make them look like the original object. It allowed sharing the GPU and multiple CPU cores for producing high-quality scenes with perfectly round spheres, shadows and ambient lighting. For changes in the position of the light source, the texture is updated from a collection of 200 different pre-rendered views. Using this approach, YASARA View can display larger complexes on smartphones as well.

NGL Viewer (2015)

With HTML5 feature set and tremendous performance gains of JavaScript, web-browsers have now become more powerful in integrating GPU accelerated image processing, physics and other graphical effects as part of the web page canvas (Yuan *et al.*, 2017). This is due to the development and integration of a JavaScript based Web Graphics Library (WebGL) into modern compatible browsers. WebGL renders interactive 2D and 3D graphics without the use of plug-ins. NGL Viewer makes use of this capability of web browsers to interactively display molecular structures (Rose and Hildebrand, 2015). It can create rich visualization for common structural file formats like PDB, GRO or mmCIF using various molecular representations like *line*, *point*, *cartoon*, *space fill*, *tube*, *ribbon*, *licorice*, etc. In order to greatly reduce the geometric complexity in displaying large macromolecules, the image rendering includes ray-casted impostors. NGL viewer can be embedded into structural database websites like RCSB PDB (see "Relevant Websites section") to allow loading, quick depiction and subsequent manipulation of molecular structures online (Rose *et al.*, 2017). In fact, only NGL Viewer is used by PDB database for structure larger than 10,000 residues (Rose *et al.*, 2016).

3Dmol.js (2015)

3Dmol.js is a pure JavaScript, hardware-accelerated, object-oriented molecular visualization library (Rego and Koes, 2015). It has been developed as an alternative to the software-based rendering of Jmol and JSmol. The major focus is online interactive visualization for molecular structures with near native performance. It uses WebGL (*as described above for NGL viewer*) which comes preinstalled in modern browsers. Therefore, 3Dmol.js does not require any additional plugin. The users can either embed the viewer or use it through a hosted viewer using a URL. It can read various file formats like pdb, sdf, mol2, xyz and cube. Its performance is at par with Jmol, JSmol.

Web3DMol (2017)

Like NGL Viewer, besides allowing interactive displays and manipulation of 3D structures, Web3DMol provides some extra functions such as sequence plot, fragment segmentation, measure tool and meta-information display for a better understanding (Shi *et al.*, 2017). Additionally, NGL Viewer does not allow rendering different parts of a protein under different modes. Web3DMol, on the other hand, can display both the primary, secondary structures and related meta-information (e.g., molecular classification, structural resolution and experimental details) for a structure. It can render different parts of a molecule as different modes using the fragment segmentation and interactively measure distances, angles and area between a group of atoms. Another interesting feature is Web3DMol's graphical display sharing using an automatically generated *sharing-URL*. Anyone can share the complete interactive behaviors such as rotating, zooming and translating, can be easily shared with others using this URL.

Additional Insights From Structure

The growth of tools that help in online rendering of structures have boosted development of several web resources that provide more insights related to protein structures. Such resources are more helpful for undergraduate students in understanding the relationship between 3D protein structure and function (Terrell and Listenberger, 2017; Hayes, 2014). With the same goal in mind, several journals now provide interactive 3D structure visualization while others have started using interactive 3D figures. However, there is nothing better than a dedicated online server or tool or database for this purpose. Below are details on some excellent tools that provide additional insights along with structural visualization.

Aquaria

Aquaria (see “Relevant Websites section”) generates a concise visual summary of all related PDB structures for any sequence or PDB structure of interest (O’Donoghue *et al.*, 2015). It is capable of loading information regarding domains, post-translational modifications or single nucleotide polymorphisms (Fig. 7). The server generates an all-against-all sequence comparison monthly from PDB and SWISS-Prot. Using this pre-calculated data or comparison, Aquaria ranks and serves the list of structures related to the sequence loaded. Using such information, Aquaria contains a median of 35 structures per protein and no other resources can match this depth of sequence-to-structure information.

PDBsum

PDBsum is a web server capable of performing various analyses that include protein secondary structure, protein-ligand and protein-DNA interactions, structural quality, among others. It is freely available at the website provided in “Relevant Websites section”. Previously, PDBsum used static images generated using PyMOL however now it uses 3Dmol.js, RasMol, Jmol, PyMOL, and Strap to display the 3D structures interactively (Schrodinger, 2015; Laskowski *et al.*, 2018; Sayle and Milner-White, 1995; Rego and Koes, 2015; Gille and Frommel, 2001). It uses the SURFNET program (Laskowski, 1995) to calculate cleft regions which can then be visualized. PDBsum provides links to homologous proteins using links to the Sequences Annotated by Structure (SAS) server (Milburn *et al.*, 1998). Secondary structure assignments and topology diagram are computed using PROMOTIF and HERA (Hutchinson and Thornton, 1990; Hutchinson and Thornton, 1996), respectively. Interactions of a protein with other proteins, ligands, or metal ions are generated using HBPLUS and LIGPLOT (Wallace *et al.*, 1995; McDonald and Thornton, 1994). PDBsum shows information related to domain architecture from Pfam and CATH (Finn *et al.*, 2016; Sillitoe *et al.*, 2015). Pores and tunnels in a protein are calculated using Mole (Sehnal *et al.*, 2013). For enzymes, PDBsum shows a reaction diagram obtained from Kyoto Encyclopedia of Genes and Genomes (KEGG) database (Kanehisa *et al.*, 2017). A subset server of PDBsum, DrugPort, identifies all “drug targets” in the PDB using the DrugBank database (Law *et al.*, 2014) and any drug molecules that occur as ligands in PDB structures.

Proteopedia

Proteopedia (available at the website provided in “Relevant Websites section”) is a collaborative effort to generate an interactive wiki-based encyclopedia for visualizing 3D structures of protein, nucleic acid and other biomolecules (Hodis *et al.*, 2008). The structural annotation here is intuitive, interactive, and the knowledgeable users can even contribute to the annotations pages in the website (like Wikipedia; see “Relevant Websites section”). It can also be used as a pedagogic tool for teaching the relationships between biomolecular structure and function in the classroom. Initially, Jmol (Hanson, 2010; Cass *et al.*, 2005) was used to display the structures but it required users to have Java installed on their computers. Therefore, Proteopedia has now shifted to JSmol, which does not require Java to be installed. There are now more than 130,000 pages in Proteopedia which have been contributed by more than 3300 users worldwide. Users can also generate content for their scientific publications using the interactive 3D visualizations while keeping these articles absolutely private so that only they may view and edit (Prilusky *et al.*, 2011).

Fig. 7 A composite image generated using multiple screenshots for Aquaria tool. Different options available in the tool have been brought together to provide a general idea of the interface. We loaded the 3ADO, rabbit gulonate dehydrogenase, crystal structure from PDB as an example.

MolviZ.Org

MolviZ.org is another similar web resource that brings together molecular visualization resources. It is available freely at the website provided in “Relevant Websites section”. It has a lot of content related to molecular visualization, for example, interactive tutorials, software related to molecular exploration, an atlas that contains images and descriptions of selected macromolecules, etc.

POLYVIEW (-2D/3D/MM)

The POLYVIEW is a 2D and 3D molecular visualization server that offers a flexible annotation tool for generating protein sequence annotations, including secondary structures, relative solvent accessibilities (RSA), functional motifs and polymorphic sites (Porollo and Meller, 2007). 2D graphical representations in a customizable format may be generated for both known protein structures and predictions obtained using protein structure prediction servers like CASP. For example, one can identify putative globular soluble as well as membrane domains to make preliminary conclusions about the domain structure of a protein (Porollo *et al.*, 2004). POLYVIEW may be used for automated generation of pictures with structural and functional annotations like secondary structure (SS) states (H, E, C), RSA, hydrophobicity, polarity and charge profiles for publications. POLYVIEW-3D, is a major update of POLYVIEW. It uses PyMol (Schrodinger, 2015) for high quality rendering of models and structures (Porollo and Meller, 2007). It can also perform advanced structure and function analysis, like mapping interaction interfaces, binding pockets, and comparison and scoring of protein docking models. POLYVIEW also provides extensive cross-linking with several rigorously validated annotation and prediction servers, such as ConSurf, CASTp, ClusPro, and SPPIDER. POLYVIEW-MM (for molecular motion) enables integration of high-quality animation, e.g., trajectories generated by molecular dynamics and related simulation techniques, with structural annotation (Porollo and Meller, 2010).

Future Applications in Molecular Visualization

The molecular visualization software for viewing 3D models is improving in terms of many aspects for example, level of details, perception of depth using lighting, etc. People from various fields like experimental biologists, database developers, computer scientists, and package developers join hands to bring about these advances. The latest and most exotic computer hardware like 3D printers that create three-dimensional objects or displays that produce stereoscopic depth without special glasses and force feedback (haptic) devices that provide a sense of touch are finding applications to molecular assemblies (Nagata *et al.*, 2002; Stocks *et al.*, 2009). With force feedback technology, the user can ‘touch’ and sense the electrostatic potential field of a protein molecule and aid in various molecular modeling approaches (Haptic-driven, 2012). A globular probe is used to scan the surface of a protein, the electrostatic forces between the protein and the probe are calculated in real-time and fed into the force feedback device (Wollacott and Merz, 2007; Bolopion *et al.*, 2010; Hou *et al.*, 2014; Subasi and Basdogan, 2006). Multi-modality enhancements of such tangible models are being created by superimposing graphical information on physical models, by adding voice commands and by providing haptic feedback (Sankaranarayanan *et al.*, 2003). However, it would require another huge space to discuss these advances in molecular visualization.

Concluding Remarks

By describing the state-of-the-art features used for structural visualization of protein and other macromolecules, this article has provided a brief overview of topic. We hope that its content successfully explains most of the concepts related to molecular visualization, especially related to biomolecules. In fact, there is a continuous need for improvement in the field as there is always new details made available by the advances in other technologies related to structure determination. This keeps creating a void which needs to be filled by more advances and improvements in the existing visualization approaches. The development of better and newer software for molecular visualization continues and keeps advancing the field.

Glossary

Coevolution coupling Extent of correlated amino acid substitutions between pairs of positions in a protein sequence.

Force field (in molecular dynamics simulations) Set of equations and parameters that describe the potential energy of a system, required to compute and propagate forces during molecular dynamics simulations.

HTML The code standard for writing web pages.

NOE restraint Restraint about upper distances between pairs of – typically – hydrogen atoms, as retrieved from the nuclear Overhauser effect in special nuclear magnetic resonance (NMR) spectra.

Site (in the context of proteins) Position in a protein's sequence, residue.

SMILES (small molecules) A computer-readable text code to encode the chemical constitution of molecules.

Introduction

Work on any protein begins by defining the exact amino acid sequence of the relevant protein form and by retrieving annotations from resources like UniProt in [Table 1](#) ([Pundir et al., 2016](#)). One can then make extensive analysis of the protein's sequence in structural and functional terms; but at the deepest residue and atomic levels, protein-specific details are best available from analyses of experimental structures or models of reasonable confidence. Such structural analyses help to readily explain biochemical observations and suggest experiments, toward the final aim of dissecting structure–function relationships for the system and a full physicochemical description of the protein's role in organismal physiology. This article deals with a variety of tools to carry out such structural analyses of proteins.

Retrieving Experimental Protein Structures and Modeling Unknown Structures for Analysis

All experimentally determined structures are deposited in a validated form at the servers of the worldwide Protein Data Bank (PDB) partnership (Table 1; Berman *et al.*, 2003), containing at the moment over 130,000 structures (Berman *et al.*, 2013). One can reach a given structure either from a PDB ID indicated in a publication, by performing a BLAST or HHpred search against the PDB, or through detailed searches in the PDB data centers themselves, which typically allow extensive filtering based on sequence similarity, the presence of specific molecules, the experimental technique used to solve the structure, structure quality parameters, etc. Note that PDB searches can yield the structure of the protein of interest itself or can yield template structures for homology modeling of the subject protein. Also, PDB searches often return structures of mutants, complexes with antibodies or small molecules, and other forms that do not correspond exactly to the isolated, native protein.

Importantly, many PDB-derived webservers and databases specialize on specific kinds of molecules and even on specific protein families, or in PDB entries containing specific interactions, or in sequence-structure or structure-dynamics relationships, etc. They are extremely useful for the structural biologist and bioinformatician, as they facilitate many kinds of analyses, as recently reviewed in Abriata (2016a).

When no experimental structures are available for the protein or assembly of interest, there are still several avenues that can be exploited to obtain at least a structural model of it, or parts of it, from various sources of information. Such modeling strategies might be exclusively computer-based or might integrate sparse experimental data with computational modeling tools (Tamo *et al.*, 2015). An excellent, up-to-date briefing on protein modeling strategies is available (Kc, 2016), while a very important resource is the collection of articles produced after each biannual critical assessment of structure prediction (CASP) competition (Molt *et al.*, 2016). Here only a brief overview of modeling methods based on protein homology, residue coevolution and *ab initio* folding is given.

Homology modeling consists in building a model of the coordinates of a protein's atoms using the experimental structure of another protein as a template, both assumed structurally similar given their high sequence similarity (Khan *et al.*, 2016). Since high sequence similarity with a good coverage of the subject sequence is needed, modeling efforts focus mainly on well-defined domains. A new emerging strategy, far less established than homology modeling but applicable when no structures of homologs are available, exploits the strong coevolution couplings undergone by pairs of residues that make contacts in folded proteins. After several works reporting the proof of concept and extended testing (Hopf *et al.*, 2012, 2014; Kamisetty *et al.*, 2013; Marks *et al.*, 2011; Morcos *et al.*, 2011; Ovchinnikov *et al.*, 2014), actual use to model structures began in the last ~2 years (Abriata, 2016b; Kassem *et al.*, 2016; Ovchinnikov *et al.*, 2015, 2017; Tian *et al.*, 2015). Some online tools like EVFold and RaptorX take a sequence as input, build an alignment from it, compute coevolution couplings and finally build 3D models. Others like Gremlin input a sequence, build an alignment and provide a list of couplings and structural restraints that can be used in external modeling programs.

Last, a series of methods attempt to fold proteins "*ab initio*" or "*de novo*" (Błaszczuk *et al.*, 2013; Bradley *et al.*, 2005; Mabrouk *et al.*, 2015; Xu and Zhang, 2012). The success rate of these methods is relatively low, so extensive external validation is important. (Plus, note that even in successful cases, the folding protocols and pathways do not necessarily mimic the true events that lead to the folded protein.) Among *ab initio* methods, there are examples based on classical molecular dynamics simulations started from extended conformations; these approaches are computationally very expensive, even if enhanced sampling methods are used, and are currently limited to peptides, although some small proteins have been folded using specialized supercomputers (Lindorff-Larsen *et al.*, 2011; Piana *et al.*, 2013).

Analyzing Protein Structures in Their Biological Contexts: Protein–Protein, Protein–Nucleic Acid and Protein–Membrane Assemblies

Very often, protein structures are determined in nonnative conditions, for example, a membrane protein is solved in micelle lipids instead of a lipid bilayer, or a protein is solved isolated but physiologically exists only within the framework of a larger assembly. One can use a number of tools to build up models of their complexes, and even high-order assemblies, using contact information from experiments or computation, and experimental data about shape and volume of the complex, even accounting for subunit dynamics (Tamo *et al.*, 2015). It is also possible to explore protein oligomerization through – for example, coarse-grain molecular dynamics simulations or docking, typically aided by or tested through mutagenesis experiments. Atomistic molecular dynamics simulations are also potentially useful but are still far from becoming routine due to the extensive sampling required, the typically large systems involved, and many shortcomings of current force fields (Abriata and Dal Peraro, 2015; Bandaranayake *et al.*, 2012; Petrov and Zagrovic, 2014); however, they have potential for scoring predicted complexes (Sarti *et al.*, 2016).

When insertion of proteins into membranes is important, there are tools that help assemble proteins into lipid bilayers, disks, micelles and other lipid-based structures (Bovigny *et al.*, 2015; Jo *et al.*, 2009; Lomize *et al.*, 2006; Stansfeld *et al.*, 2015). Some of these tools further provide starting points for simulations with popular programs. For combining even more elements, in principle with no limitations, programs like Packmol and Cellpack (Johnson *et al.*, 2015; Martinez *et al.*, 2009) become very handy. These programs facilitate the setup of atomistic or coarse-grained systems for visualization, comparison of geometries, serving as starting points for molecular dynamics simulations of complex multimolecular systems as in Spiga *et al.* (2014).

A Note on Computational Models of Proteins and Assemblies

As an important note, each computational model is useful for tasks and analysis of varying complexity depending on the approach and the quality of the underlying experimental and computational information utilized to derive it. For example, a model of a

transmembrane protein based on packing of predicted transmembrane helices will be enough to approximate how the protein embeds in biological membranes and to estimate the relative location of specific residues, especially along the membrane normal, possibly even leading to propose mutations that can be tested experimentally. However, it will very likely be unstable in atomistic molecular dynamics simulations and certainly will not serve for docking or virtual screening campaigns.

Alignments in a Structural Context

It is standard practice in biology to think about a subject protein in the context of its family, as this helps to identify residues that are ultimately important for the protein to achieve its function. Moreover, protein 3D structures are conserved much more than their sequences, such that highly similar structures often imply a similar function, which is very important for function prediction of new protein sequences.

These observations have practical parallels in structural bioinformatics, with the advantage that (1) typically much larger numbers of related sequences are analyzed, and – as a consequence of this – (2) that specific reasons for why different amino acids are more or less tolerated at each position can be explored deeply. The second advantage stems from an often overlooked aspect of amino acid variation in proteins, namely that the probability of observing a given substitution in a given condition arises as the combination of a variety of factors that can be affected on top of effects on function itself. The list includes trivial deleterious effects of mutations at active site residues and well-known effects on the stability of the protein, but also effects on protein internal dynamics (González *et al.*, 2016), on the response to unexpected interactions forced at high concentrations (Abriata *et al.*, 2016a), and even effects not directly related to the protein itself, for example, at the transcription level (Weatheritt and Babu, 2013). Moreover, substitutions at multiple sites are often coupled through structural constraints or might display nonadditive effects on some protein traits, facts that often contain structural and functional information. Keeping all these points in mind while analyzing alignments is hard, but as shown in this section many computational tools help to understand some of these effects and thus gain more insights into the subject protein.

On one hand, the new methods for calculating *de novo* protein structures and protein complexes from coevolution patterns as described above, have also proved powerful to find out relevant alternative protein conformations (Morcos *et al.*, 2013). Therefore, given a protein structure or model, mapping of contacts predicted through coevolution methods can reveal alternative conformations of functional significance (Table 2). On the other hand, alignments that are consistent with structure according to residue coevolution analysis have also proved informative about the physical and biological chemistry that underlie sequence variation in the family, in such a way that helps to derive structural and functional information (Abriata *et al.*, 2016b). The PsychoProt webserver, originally developed to dissect amino acid variability from deep-sequence-based experiments on saturated mutational libraries (Abriata *et al.*, 2015), helps to easily quantify conservation and variability throughout a protein's sequence and structure and to extract structural and functional information about the protein. For example, PsychoProt can easily unveil polarity/hydrophobicity requirements in soluble and transmembrane proteins, or residues that evolve under functionally relevant constraints for steric hindrance or conformational dynamics. Such kind of analysis is useful for augmenting the amount of information of both experimental structures and models, as well as to justify the position of hydrophobic and polar amino acids in models and to hypothesize about a protein's dynamic features and functional elements.

Tools for Analysis of Protein Structures and Models

This section focuses on two main kinds of analysis one can perform on structures and models. On one hand, treated first, one can (and should, for many applications) check the quality of the structural information; on the other hand, there are those analyses that deal with extracting information from the models.

Checking the Qualities of Experimental and Modeled Structures

Quality checks are important to estimate how well the protein structure or model satisfies the known geometries and the underlying data. These checks are critical when atomic-level details affect the interpretation or further studies that one wants to achieve from the structure or model. This is the case when, for example, setting up systems for molecular docking, virtual screening and molecular dynamics simulations; but on the other hand is less of a problem, for example, for mapping nuclear magnetic resonance (NMR) data on a model or structure, or if a model/structure is used for solving the X-ray structure of a related protein through molecular replacement.

A large array of tools (RPF, PROCHECK, MolProbity, Verify3D, Prosa, WHAT_CHECK, ERRAT, PROVE (Chen *et al.*, 2010; Colovos and Yeates, 1993; Eisenberg *et al.*, 1997; Huang *et al.*, 2012; Wiederstein and Sippl, 2007; Willard *et al.*, 2003) exist that check for geometries and chemistry, such as reasonable backbone and side chain dihedrals, correct stereochemistry, correct packing without clashes, fulfilment of hydrogen-bonding networks, swapped side chains, etc. Other tools are more specialized for checking the quality of the structures in relation to the underlying X-ray or NMR data. Many of these geometry-, chemistry- and data-related tests are actually compulsory upon submission of new structures to the PDB, which is required to ensure the good quality of PDB

entries, derived experimentally. It must be said on the other hand, though, that as shown in recent CASP experiments, computational models of better geometry/chemistry scores do not warrant agreement to “true” structures.

Most checking tools are available as servers, and moreover there are servers that integrate multiple tools: PSVS, SAVES, PROSESS, VADAR, CING, ResProx, Vivaldi (Berjanskii *et al.*, 2010, 2012; Bhattacharya *et al.*, 2007; Doreleijers *et al.*, 2012; Hendrickx *et al.*, 2013). Some servers, notably MolProbity, return an overall score that puts together different quality statistics, in this case such that lower numbers overall indicate “better” structures.

For initial checks on specific PDB entries, there are databases of precomputed quality checks (Hooft *et al.*, 1996) and of optimized PDB entries (Joosten *et al.*, 2014). Yet other servers focus on specific problems structures might suffer from, for example, on the refinement of metal sites (Zheng *et al.*, 2014), on trans-cis, amide side chain and peptide plane flips (Touw *et al.*, 2015; Weichenberger and Sippl, 2007), etc.

Visualization of Biomolecular Structures and Models

Moving on to the second kind of structural analyses, more directed to extract information out of the experimental or modeled structure, there are several questions that computational approaches can solve or at least shed light into. These include analysis of structural features such as surface properties, electrostatics, dynamics; identification of active sites, allosteric sites and interaction sites, mapping of conserved and variable regions, testing for the effects of mutations, measuring the degree of exposure of given residues, etc.

Visualization of molecular structures is key to work in structural biology, and a key step of structural analysis. Moreover, careful inspection of structures and models is critical before running automated analysis or molecular dynamics simulations on them, especially to highlight problems that are invisible to the analyses and could actually introduce errors on their results.

Among the most popular visualization tools that are free for academics, there are COOT (especially suited for working with X-ray data), MOLMOL (specialized for NMR structures), VMD (mainly tailored to setup and analyze MD simulations), PyMOL and Chimera (both with very simple ways to model secondary structures and nonnatural groups and to get stunning images). Many of these visualization programs actually do much more than displaying structures, containing tens of commands for molecular building and analysis. With some advanced knowledge of these tools one can also create detailed movies; on the other hand, simple movies about rotations, morphing and vibrations among other few possibilities, can be rendered online with the MovieMaker webserver (Maiti *et al.*, 2005).

Nowadays, integration of biomolecular structures directly inside HTML for online visualization without plug-ins is possible thanks to tools like JSmol (Hanson *et al.*, 2013), PV, GLmol (Virag *et al.*, 2016), 3dmol.js (Rego and Koes, 2015), Molmil (Bekker *et al.*, 2016), Litemol, and the NGLviewer (Rose and Hildebrand, 2015) soon to be updated to handle large macromolecular complexes online (Rose *et al.*, 2016). Such tools make it extremely easy to openly share customized, interactive 3D views of molecules (see Relevant Websites).

Properties of Protein Surfaces and Cores

The physicochemical properties of a protein's core and surface are important to its stability, particularly regarding solubility, and to its interactions with specific substrates and proteins or with other solutes present at high concentrations in crowded media. An easy first qualitative look at a protein's surface properties is to simply inspect its surface colored by residue type in any visualization program, or more quantitatively, by mapping the amino acid hydrophobic moments on the protein surface (Eisenberg *et al.*, 1984). You expect mostly polar and charged amino acids at the surface of a globular soluble protein, and mostly hydrophobic amino acids in membrane-embedded regions. Patches of inconsistent polarity point at sites of potential functional importance (e.g., for protein-protein interactions) or that can be mutated to improve solubility (e.g., in an enzyme) or simply to errors in the case of models. Note that a given protein might contain an isolated amino acid that does not match polarity requirements while the whole family does contain information about the correct polarity preferred at the position; here is where the joint analysis of alignments in the context of protein structures with tools like PsychoProt as mentioned above (Abriata *et al.*, 2016b) becomes useful. Last, there are also tools to simplify visualization and comparison of the shape and physicochemical features of protein surfaces through mapping in 2D (Yang *et al.*, 2012).

Closely related to surface polarity is the global electrostatics of a protein or complex (Dong *et al.*, 2008). The APBS program and online server (Baker *et al.*, 2001) computes electrostatic fields and electrostatic surface maps from the coordinates of a molecular system, which can be visualized easily in programs like PyMOL and VMD. This requires assignment of charges to all atoms, which can be carried out with PDB2PQR (Dolinsky *et al.*, 2007) through a handful of charge models and which might in turn require assessment of the protonation states of several groups as automatically carried out by PROPKA (Olsson *et al.*, 2011). The main PDB2PQR server (Unni *et al.*, 2011) performs all these calculations, in its simplest mode taking a PDB file and returning an APBS file for visualization (as electrostatic surfaces or fields) in external programs like PyMOL and VMD. VMD can also itself calculate the electric moment of a selection of atoms, which can then be used to track its evolution over time.

Regarding protein cores, structure-based analyses of alignments with PsychoProt revealed that not only hydrophobicity is required in a protein's interior but also precise combinations of volume and steric hindrance, adorned with regions of certain flexibility or conformational preferences closer to the protein surface (Abriata *et al.*, 2015, 2016b). Stability of the core of globular proteins upon mutation can be tested with tools like FoldX, I-Mutant, Dmutant, PopMusic and Rosetta, among others. These programs tend to be better predictors of destabilizing than stabilizing mutations (for an assessment of different tools see (Khan and Vihinen, 2010)). Last, another informative way to test packing in a protein structure or model is to compare its contact map to the coevolutionary couplings computed from a related alignment (tools for this are available in Table 2).

As a final point, for precise quantification of solvent accessibility, programs like VMD have built-in functions that can easily be executed on multiple structures or on simulation trajectories, while servers like POPS (Cavallo *et al.*, 2003) provide easier ways to run the calculation but on single structures.

Small-Molecule Pockets and Protein-Small Molecule Interactions

Testing the interactions between small molecules and proteins requires special treatments, and the procedure is usually split into finding pockets where small molecules can fit, and finding how small molecules can bind to it.

Many tools allow users to search for potential small molecule-binding sites in protein structures. Among them, fpocket (Schmidtke *et al.*, 2010) implements a high-performance algorithm which allows detection and tracking of pockets in large ensembles of structures or molecular dynamics trajectories. Another very recent and complete tool, PockDrug (Hussein *et al.*, 2015), is a server specialized in finding druggable pockets, which inputs a PDB file and returns the detected pockets with complete physicochemical descriptions plus scores that estimate how druggable they are.

Once a druggable pocket has been identified in a protein, or if it is already known, one can choose among a large list of academic and paid programs for docking small molecules to the target pockets (full searches are also possible but much more time consuming and leading to less significant results). These programs can be used to test how a given molecule would dock in a pocket, often called “virtual docking,” and can be run iteratively on a library to predict which molecules are expected to bind stronger, often called “virtual screening.” It is important that such campaigns usually seek to enrich libraries in drug leads and potentially active molecules, but are currently not capable of delivering definitive answers on the perfect drug for a given pocket. For a recent review of potentials and limitations for realistic uses in biology, see Forli (2015), Irwin and Shoichet (2016). For the special case of docking peptides as small molecules onto proteins, there are specialized tools from the Rosetta and HADDOCK families (London *et al.*, 2011; Spiliotopoulos *et al.*, 2016).

Note that there are many challenges in the field of docking and virtual screening, related to poor sampling of flexibility especially in the target protein and to overlooked or only poorly described effects of water (Spyrakis and Cavasotto, 2015). Such problems could in principle be solved by using atomistic molecular dynamics simulations; however, they are orders of magnitude more expensive and hence currently outperformed by docking-based methods, although they are increasingly becoming useful to score poses obtained through docking-based methods (for a thorough discussion on the role of molecular dynamics simulations in drug discovery, see De Vivo *et al.* (2016).

Regarding the structural universe of small molecules, among the most important servers for structural research there are some (with Chemicalize.org (Southan and Stracz, 2013) and CORINA standing out) that facilitate conversion between compound names, SMILES codes, 2D schemes and 3D structures of small molecules, some of them linking directly to existing annotations and retrieving or computing on-the-fly physicochemical descriptors for the small molecules. Other resources for small molecules act as mere databases of small molecules, useful along the drug discovery process, such as ZINC and PubChem (Irwin and Shoichet, 2005; Kim *et al.*, 2016).

Dynamics From Structures

Experimentally, protein dynamics are accessible at the residue level from crystallographic B-factors if properly analyzed (see the B-factor DataBase (Touw and Vriend, 2014)) and from NMR ^{15}N relaxation (note that simply variability in NMR structures is not a good indication of dynamics). Computationally, the ultimate tool is provided by atomistic molecular dynamics simulations, but such methods are costly and often unnecessary if only identification of flexible regions is required.

It is possible to predict flexibility as “disorder” from sequences with variable confidence, or to inspect a sequence manually by mapping coil propensity and other amino acid descriptors with programs like ProtScale (Table 2). Meanwhile, analysis of alignments with tools like PsychoProt can point at residues where amino acids of small volumes, low steric hindrance, large flexibility or low conformational preference are better tolerated, again indicating dynamics.

Adding a structural level to improve confidence, there are programs that predict flexible regions from structures. Some of them exploit the fact that regions of low atomic packing or high solvent accessibility tend to be more flexible (Marsh, 2013), whereas others like PDBFlex (Hrabe *et al.*, 2016) are based on the comparison of PDB entries for related proteins or even same proteins crystallized in different conditions. Another tool especially useful to identify domain motions mediated by loops acting as hinges is Normal Mode Analysis, implemented together with other related tools in the program ProDy (Bakan *et al.*, 2011). Last and probably highest in detail but only reporting on loops, a tool developed by the Bruschweiler group from a dataset of sub-microsecond MD simulations validated with NMR data, looks directly at protein loops in a structure returning their predicted flexibility and motion timescales (Gu *et al.*, 2015).

Predicting Active Sites and Functions

Prediction of function for a novel protein, or of even subtle functional changes upon mutation or upon interactions, are particularly challenging even if experimental structures are available. While annotation databases or deep searching on Pubmed, for example, with text-mining tools like ChiliBot (Chen and Sharp, 2004) can lead to functional hints directly from written information, there are also tools that can propose approximate functions from sequences and structures. The critical assessment of functional annotation (CAFA) regularly evaluates the state of function evaluation methods from information at the sequence level (Wass *et al.*, 2014), which includes methods based on sequence comparison, on co-occurrence in operons, regulons and genomes, on analysis of gene fusions, on protein colocation, and on structure. Other efforts and groups focus specifically on predicting function from structures, as briefly covered here.

Methods for predicting protein function from sequence and structural homology have been around for some time, as reviewed by Petrey *et al.* (2015). They perform reasonably well at least at the level of broadly defining function, but cannot give precisions on, for example, the exact substrates of enzymes, which is often very sensitive to point mutations (Abriata *et al.*, 2012). As a proxy for function assignment, many programs actually predict ligand-binding sites through comparison with known data, as recently

evaluated in a subcategory of CASP10 (Gallo Cassarino *et al.*, 2014). Some modeling servers like I-TASSER actually provide such analysis on their top models.

When a large alignment is available, there is evidence that gradients of amino acid substitution rates mapped on an enzyme's structure can approximate the location of its active site (Jack *et al.*, 2016), which one might better define through experimental evaluation of mutants of the most conserved residues. One can also analyze what physicochemical properties shape the preference for each of the 20 amino acids at each position of the alignment, with tools like the PsychoProt server, under the premise that preferences for flexibility, steric hindrance, volumes and backbone conformational descriptors could hint at functionally relevant regions of a protein as exemplified in Abriata *et al.* (2016b).

Data Mining

The far end within the field of computational analysis of protein structures consists in (semi)automated mining of PDB entries, either on the full PDB or on PDB-derived databases. Mining the PDB with the help of clever connections to other sources of information, powerful analytical methods, and often using specialized sub-databases, has brought to light several fine details about protein structure, dynamics and hydration, features of transmembrane proteins, metal centers, cofactor and ligand binding, and noncovalent interactions between biomolecules (a few examples among a few hundred such works in the last decade: (Gallivan and Dougherty, 1999; Jackson *et al.*, 2007; Kumar and Balaji, 2014; Lanzarotti *et al.*, 2011; Ringer *et al.*, 2007; Shi *et al.*, 2002; Valley *et al.*, 2012)). But also, mining studies can disclose effects of different experimental methods, diffraction resolution, processing software, etc. (Abriata, 2012, 2013; Djinojic-Carugo and Carugo, 2015; Harding, 2002).

Mining protocols usually involve writing specific programs and scripts for the analysis of interest, but tools aimed at simplifying mining exist (Sehna *et al.*, 2015; Valasatava *et al.*, 2014).

Comparing Structures in 3D

Comparison of biomolecular structures is at the heart of structural biology, as this science attempts to explain function in relation to structure, for example, when classifying domains, inferring function from structure, modeling proteins from homologs, and at higher level of detail when explaining functional differences as consequences of structural differences.

The problem of comparing two structures has two main steps, namely the detection of similar elements in both structures, which are to be superimposed upon alignment, and the subsequent computation that aligns the coordinates of the proteins based on such similarities. Multiple structure alignments usually start by computing all possible pairwise alignments, and then running a global optimization.

At the computer, most visualization tools allow the user to align and compare structures in 3D with simple methods that work fairly well when there is obvious similarity. However, more complex protocols are available from *ad hoc* programs and servers. Among the most widely used, currently up-to-date tools, there are CE, DALI, FATCAT and FATCAT POSA, MAMMOTH, SALIGN, SSP, TopMatch, TM-align and VAST/VAST+ (Holm and Laakso, 2016; Madej *et al.*, 2014; Ortiz *et al.*, 2002; Shindyalov and Bourne, 2001; Sippl and Wiederstein, 2008; Ye and Godzik, 2004a, 2004b; Zhang and Skolnick, 2005). It is important to highlight that different programs usually incur in inconsistencies among each other, even for relatively similar proteins (Sadowski and Taylor, 2012). Some of these tools allow comparisons between multiple provided structures, others (most notably DALI) allow querying a structure against all PDB entries; some facilitate instant online visualization; and in particular, FATCAT includes internal flexibility in its alignments, with a version (POSA) for multiple protein comparisons and another for scanning structural databases. The RCSB PDB currently facilitates online pairwise comparisons of its entries through some of these programs.

Other More Specific Analyses

A multitude of computational tools are continuously developed tailored to more specific questions, tasks and molecules. Examples are the Protein Knot Server to detect knots in structures (Kolesov *et al.*, 2007), the CheckMyMetal server to validate metal ions in protein structures (Zheng *et al.*, 2014), servers for advanced superposition and 3d-searching of proteins structures (Holm and Rosenström, 2010; Maiti *et al.*, 2004), structural databases containing precomputed descriptions for specific molecules (Abriata, 2016a), servers to predict spectroscopic observables like circular dichroism and NMR spectra from protein structures (Bulheller and Hirst, 2009; Han *et al.*, 2011), servers to validate protein structures and quantify their qualities (Willard *et al.*, 2003), and certainly much more.

A Glance at the Power of Molecular Simulation Methods

This article has focused on modeling and analyzing static structures; however, macromolecules undergo dynamics over orders-of-magnitude timescales ranging from the fastest pico-to-nanosecond vibrations to the slowest loop motions relevant for catalysis and allostery, conformational transitions, breathing motions and folding events in the microsecond to second timescales. Understanding protein folding, function, regulation, interactions, assembly processes, etc. requires consideration of these dynamic features of molecules, for which computational molecular simulations are as important as experiments. Moreover, simulations have the potential to embrace most other kinds of analysis, for example, predicting secondary and even tertiary structures through

folding simulations, predicting small-molecule binding even after free diffusion, exploring reactivity, etc., although far much less efficiently and not necessarily more accurately due to problems in the force fields.

The most important tools to study protein dynamics can be split into those based on quantum methods (which allow probing bond breaking and formation, i.e., reactions, as well as energy-exchange processes related to spectroscopic observables), and those based on classical molecular mechanics either at all-atom level (where bonds cannot be broken or formed, but all interatomic dynamics are accessible allowing the sampling of conformational dynamics) or at coarse-grain level (where atoms are grouped into beads of variable size according to the coarse-graining scheme, loosing atomic detail but allowing for extended diffusional sampling). The three levels of detail can in turn be mixed, being particularly popular in structural biology the combination of atomistic molecular mechanics with quantum-level calculations (QM/MM) to study, for example, enzyme catalysis.

Note that one way or another, all simulations methods require parametrizations (most importantly in the form of force fields for classical molecular mechanics simulations, or orbital descriptions in quantum calculations) and assumptions on how to calculate and propagate forces. Therefore, just like results from most other computational tools, results from simulations need to be tested against experimental data, or eventually taken as mere predictions to guide experiments or explain existing results. Classical dynamics can, for example, be compared against NMR dynamic data, quantum calculations can be tested by predicting and comparing spectroscopic observables.

For classical dynamics, several force fields and functional forms are available to treat proteins, nucleic acids, and some ions and lipids. If small molecules are to be used in molecular dynamics simulations, there are a few online databases of ready-to-use parameter files and also online tools that assist in parametrization (Kirschner *et al.*, 2008; Mallocci *et al.*, 2015; Zoete *et al.*, 2011) and building complex systems (Bovigny *et al.*, 2015; Jo *et al.*, 2009; Martinez *et al.*, 2009).
